PROGRESS IN THE CONTROL OF INFECTIOUS DISEASES.[1]

BY WILLIAM C. DEMING, M.D.,

WESTCHESTER, NEW YORK CITY.

THE purpose of this paper is to show, from available statistics, whether there has been in recent times any notable reduction in the mortality rates of phthisis, diphtheria, scarlet fever, and typhoid fever in this and other countries. From the results of the inquiry we may be able to infer how effective our preventive measures have been against these diseases.

In a lecture on vital statistics, in 1889, Dr. Billings said: "So far as statistics show, it does not appear that there is any difference in the mortality rate of most infectious diseases from what it used to be."[2] And only six years ago a well-known physician of New York told me that he questioned whether typhoid fever and tuberculosis, and, inferentially, the other infectious diseases, were yet diminished as a result of greater knowledge of the conditions that favor their spread and by the operation of sanitary measures.

I remember that I did not feel greatly surprised at this statement at that time, but I believe that any one of us would now affirm a contrary opinion. Our impressions certainly are to the effect that these diseases are perceptibly yielding to the advancement of knowledge and the spread of sanitary science.

The examination of the "mortality rate"—that is, the proportion of deaths from the disease under examination to each ten thousand of the population—has seemed to offer the best opportunity for getting results of value, since exact figures as to the number of cases of a disease are seldom available, and the "death rate"—obtained by comparing the number of deaths from any one disease with the total number of deaths from all causes—is subject to misleading variation.

Chart No. 1.—Mortality Rates for New York City.

The "mortality rate," however, does not show the varying "fatality" or "case fatality"—*i.e.*, the proportion of deaths to the whole number of cases of any one disease; so that it is possible for a disease to be epidemic, in a not very fatal form, without its being evident in the mortality rate. Nor does it differentiate a reduced mortality rate due to improved treatment from that due to diminished prevalence of a disease. It should always be borne in mind, therefore, that these statistics relate only to deaths and not to cases.

The figures given, while not being at all exhaustive, relate to populations large and varied enough to eliminate mere chance results. For the sake of brevity the report is limited to certain of the more complete and important sets of figures, and of these I have made charts, as results are shown so much more

[1] Read before the Hospital Graduates' Club, March 25, 1897.
[2] Quoted in the Report of the New Jersey State Board of Health for 1894.

clearly and quickly in that way. On these charts each small square indicates, from below upward, one death

Chart No. 2.—Mortality Rates for Massachusetts (and for Phthisis in Glasgow).

per ten thousand inhabitants; and from left to right, one year in time.

Diphtheria.—Considering first diphtheria and croup (here treated under the single head "diphtheria" unless otherwise stated), Chart No. 1, for New York City, giving the mortality rate for this disease from 1804 to 1896, is shown. These rates are calculated from the yearly deaths and enumerated or estimated population, as given by Dr. Nagle from the records of the board of health, with the figures since 1894 added by me from the same source. Before 1851, whenever burial took place within the city limits, registration of death was not required, and it cannot be told how near the truth the figures are before that date. From 1851 to 1866, death returns were still far from exact. It was at that time the custom of the city inspector to leave signed blank death certificates at convenient saloons and other places. From 1866, however, when the present New York City board of health was established, the returns have been accurate.

Up to 1857 this record shows only cases called "croup." During that and the following year a few cases of malignant sore throat were recorded, and in 1859 diphtheria was first tabulated. Four years later, in 1863, the diphtheria mortality rate had reached the very high figure of nearly twenty-five per ten thousand. In the period 1867 to 1871 it had fallen lower than it had been for the previous sixteen years (except in 1858), and also, what is more remarkable, much lower than it has ever been since.

Following this comes a series of four rises and four falls, the first rise, in 1875, reaching the record point of nearly thirty deaths per ten thousand population. These epidemic apices occur at intervals of six years, except the last two, which are seven years apart, each successively falling to a lower point. The depressions also show a tendency to decline, the lowest point being reached in 1896—which is, however, not so low as that of the period 1867 to 1871, and but little below that of 1879. It is also to be observed that the fall in 1895 and 1896 comes apparently at a time when it might be expected.

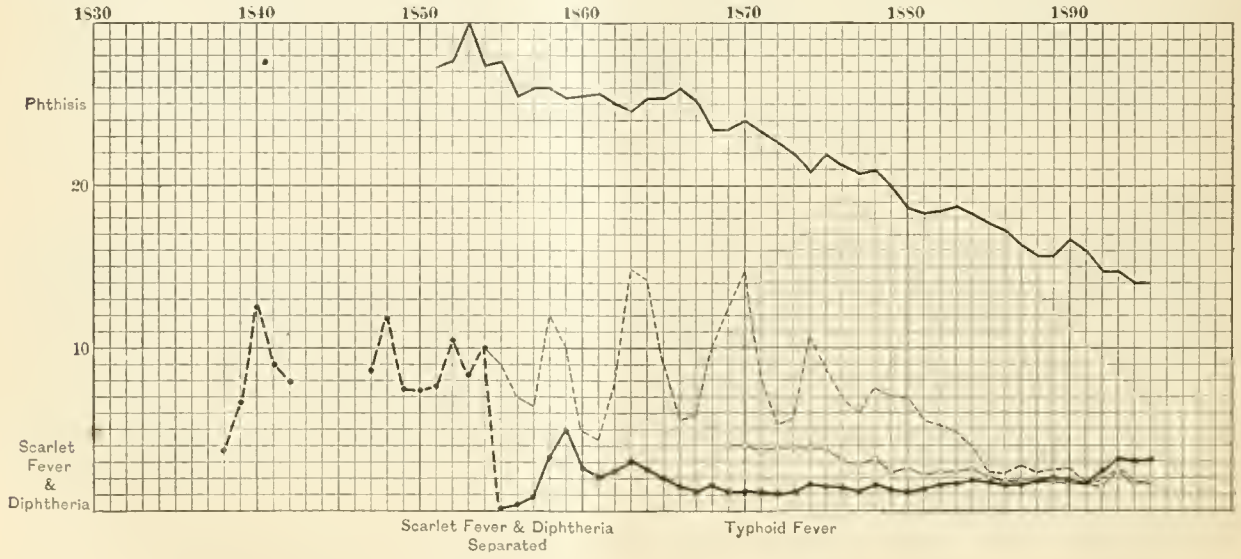

Chart No. 3.—Mortality Rates for England and Wales.

The steady lowering of the epidemic apices gives reason for the belief that sanitary measures have had their effect, this period covering the last twenty-one

years of the thirty years of existence of the board of health.

Chart No. 2 shows the mortality rate for diphtheria

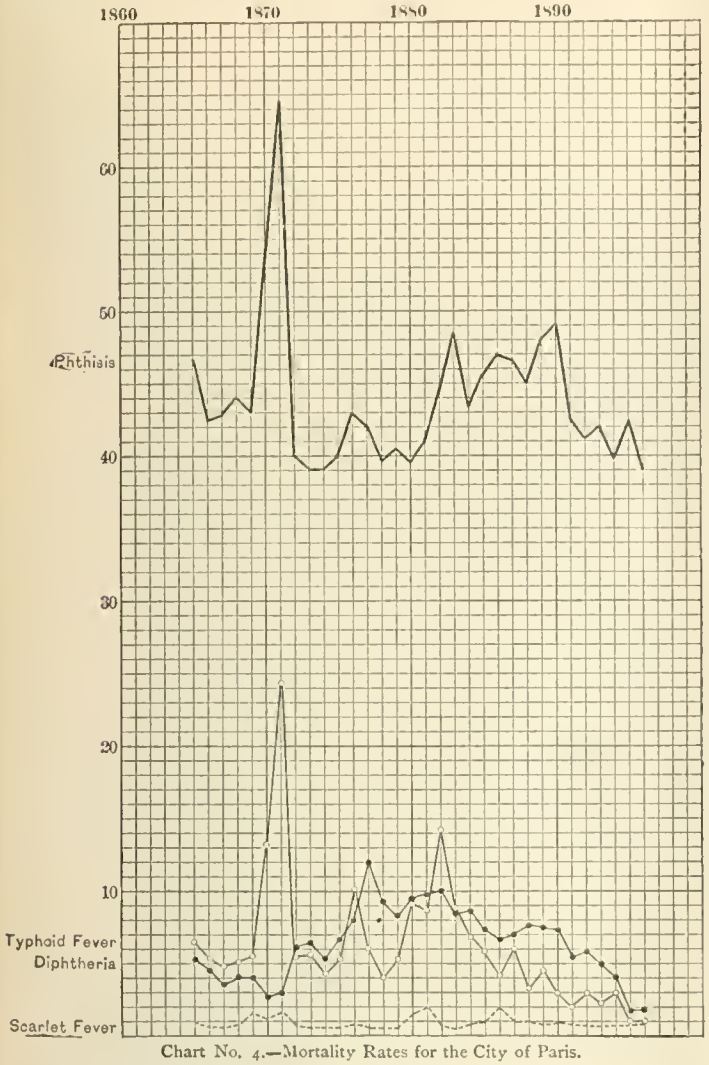

Chart No. 4.—Mortality Rates for the City of Paris.

in Massachusetts from 1850 to 1895. It follows the chart compiled by Dr. J. F. A. Adams,[1] completed from the year 1890 by figures taken from the reports of the Massachusetts State board of health. Dr. Adams says that Massachusetts was the first State to establish a board of health (about 1870), that the trustworthiness of the Massachusetts registration reports is generally conceded, and that nowhere else in the United States are the conditions so favorable for estimating the value of public-health measures.

Here we observe, in the curve for diphtheria, two great epidemic waves, in 1863 and 1876, and the apparently aborted tendency toward a third in 1889—the intervals between them being thirteen years.

Since 1876 the fall has been fairly steady, but the average for the last five years is not so low as that for the six years from 1867 to 1873 and the period from 1850 to 1859.

Chart No. 3 shows the diphtheria mortality rate for England and Wales from 1855 to 1895, taken from the figures given by the registrar-general. From 1859 to 1872 the yearly rates show a steady and marked reduction, since which date there has been a rise, especially during the period from 1892 to 1895. Although it is not my intention in this paper to compare the mortality rates of different localities, since so many varying factors must be taken into account that deductions are apt to be deceptive, yet it seems fair to do so in the case of England and Massachusetts, thus making evident the much lower and less fluctuating rate in the first-mentioned country.

Chart No. 4 shows the mortality rate for the city of Paris, from figures prepared by Dr. Bertillon. The remarkable reduction in the mortality rate of diphtheria in the last five years, and especially in the last two, is apparent. From this chart it can be seen that in 1870 and 1871 the mortality in Paris was lower than at any subsequent time until 1895, and that, too, during the Franco-Prussian war and the siege of Paris, when the mortality from some of the other infectious diseases rose enormously.

From the chart for England it is evident that the mortality was at about its lowest average during the same period (1870 to 1872). Also from the Massachusetts chart the mortality is seen to have been lower from 1867 to 1873 than at any time since, and the same feature is apparent on the chart for New York City from 1867 to 1871. In Michigan as well, in 1869 to 1871, the mortality was far lower than it has ever been since (1869, 1.7; 1870, 2.09; 1871, 2.25; the rate for 1893 being 5.52). The same is true for Rhode Island from 1868 to 1870. The report of the Chicago health department for 1895 and 1896 gives the lowest mortality rate for diphtheria ever there recorded, in the period 1871–1875.

So we find indicated for the period about 1870 an extremely diminished mortality rate, very wide spread, lower than at any subsequent time, apparently without the operation of any special treatment or sanitary measures. This low point was preceded and followed by periods of high mortality, and there are evidences of a still earlier period of low mortality, though records are too defective for exact determination of this question.

There is thus suggested the idea of cycles of from twenty to twenty-five years in length in the life history of this disease, independent of the

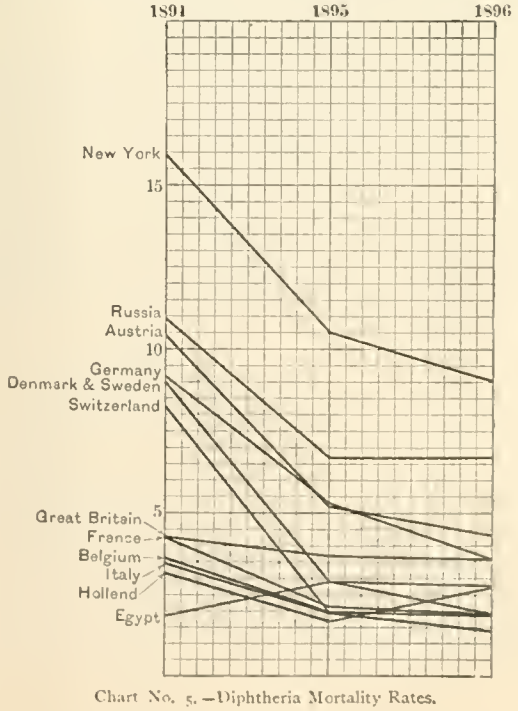

Chart No. 5.—Diphtheria Mortality Rates.

periodical epidemic fluctuations generally attributed to variation in the number of susceptible individuals.

[1] Boston Medical and Surgical Journal, July 14, 1892, p. 29.

This may possibly be the result of a partial immunization of alternate generations of the population. It is also apparent that a period of decline is now due, and the suggestion of a cycle of rise and fall is especially interesting at this time of universal reduction of the mortality rate coincident with the use of antitoxin.

This universal fall is well shown on Chart No. 5 (amplified), following the published figures of Dr.

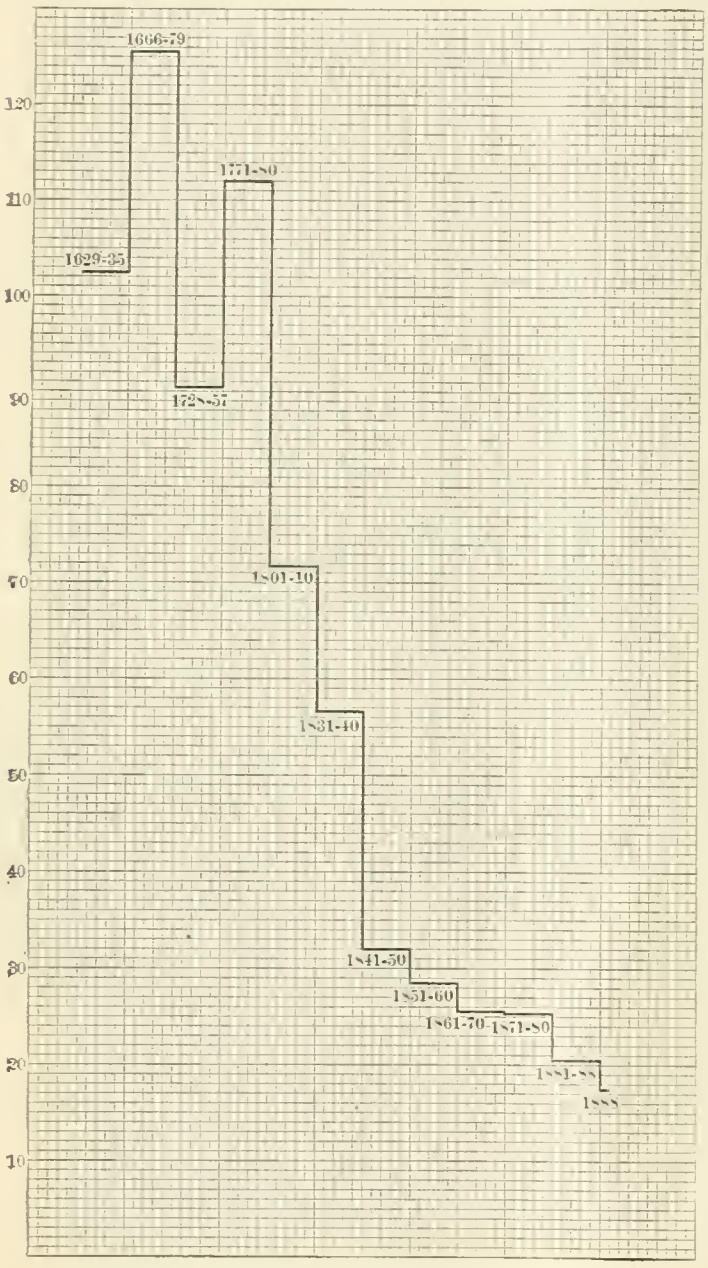

Chart No. 6.—Mortality Rate for Phthisis in the City of London.

Biggs and Dr. Guerard, which represents the mortality rate in cities of over one hundred thousand inhabitants throughout a large part of the civilized world for the years 1895 and 1896. One is struck by the unenviable position of New York, far at the top of the list, the rate for that city standing, in spite of its remarkable fall, still nearly as high as the highest of the others before the fall began. Of course allowance must be made for the fact that New York is a city of much greater population than the average population of the other cities, but even then the disparity remains striking.

Scarlet Fever. — In Chart No. 2 the dotted line shows the improvement in the mortality rate of scarlet fever in Massachusetts, making it clear that the epidemic waves, which recurred every four to six years from 1853 to 1875, have quite steadily diminished in height since 1857, that the depressions have shown the same tendency, and that since 1875 the epidemic waves are scarcely perceptible and the mortality rate has fallen to a very low point.

Even more marked is the steady fall of the mortality rate from scarlet fever in England (Chart No. 3), the rate of 1.5 in 1895 being the lowest ever there recorded. This line falls below those of diphtheria and typhoid fever, so that from being by far the highest of all it is now the lowest. The decline in the mortality rate of scarlet fever in Chicago is phenomenal. From epidemic fluctuations rising as high as 19.05 to 27.20 in the years preceding 1878, it has steadily fallen since then to the record point of 0.33 in 1896.

In New York City (Chart No. 1) at the present time the mortality rate has fallen to a point not reached since the period from 1845 to 1850, when from some cause the rate was even lower than it is now, thus suggesting again for this disease also the idea of a cyclical rise and fall. In Michigan there has been a marked and quite steady decline from 7.20 in 1870 to 1.63 in 1893. Dr. Baker says that the mortality from scarlet fever in Michigan has been only one-half of what it was before the systematic operation of sanitary measures. New Hampshire shows a remarkable and fairly steady drop of from 1.44 in 1884 to less than 0.15 per 10,000 in 1895—"chiefly if not solely by sanitary regulations." Rhode Island reports for 1870 a rate of 3.5; 1880, 16.92 (epidemic): 1881 to 1885, 2.8; 1886 to 1890, 3.8: 1891 to 1892, 1.4—a marked reduction. In Ireland, for the ten years from 1871 to 1880, the rate was 4.359; in the ten years from 1877 to 1886 it fell to 2.75, and then gradually to 0.66 in 1891, from which point it has again risen to 1.29 in 1895. In Hamburg the number of deaths from scarlatina was lower in 1895 than in any year since 1888 (the second year following an epidemic). In Paris (Chart No. 4) the constant extremely low mortality rate of scarlet fever is very remarkable.

It is interesting to note Dr. Farr's statement that "Sydenham (who wrote from 1666 to 1683) describes simple scarlatina distinctly: he does not refer to the throat affection, and says the patient can die only by the doctor's default;" and that "Joseph Frank describes the disease now (1869) as the most dreadful scourge in Europe."[1] Again there is, as noticed in diphtheria, the suggestion of a cyclical rise and fall in mortality or occurrence. This has been studied by Dr. Ransome, who has constructed, from the Swedish tables of mortality, charts showing cycles in this disease.[2]

It is a common impression at the present time that scarlet fever is a disease of diminishing prevalence and increasing mildness. This, if true, may be only the result of a waning epidemic influence, to be followed sooner or later by a rising one. But since we find that our impression is confirmed by the figures gathered from many parts of the world, especially from those places where sanitation is best enforced, we may indulge the belief that the diminished prevalence and severity are due to sanitary efforts and are permanent. Unfortunately we cannot obtain reliable figures from extensive areas where sanitation is not enforced, to learn if the diminution also prevails in such places.

[1] "Vital Statistics," p. 324.
[2] Transactions of the Epidemiological Society, 1881–82.

It is not unlikely, it is even probable, that the germ of scarlet fever is less viable than that of some of the other diseases, and that stricter observance of isolation and disinfection is beginning to have a permanent effect on its dissemination and its virulence. It is to be observed that in warmer climates there is a much smaller incidence of scarlet fever, and the same is true with us during the warm months, the reason for which is probably that more sunlight, better ventilation, and more outdoor life, aside from the influence of the closing of schools in summer, have a strong inhibitive effect on the development of the germ.

Phthisis.—When the figures for phthisis are charted we obtain some very uniform results. On Chart No. 2 are shown the curves for Massachusetts and for Glasgow from charts of Dr. Adams[1] and figures given by James B. Russell.[2] Massachusetts shows a fall in the mortality rate from 42.5 in 1853 to 21.7 in 1895. In Glasgow the decline did not begin until 1871, but since that time it has kept pace closely with that in Massachusetts.

In New York City (Chart No. 1) the fall is almost equally well marked. In the early part of the century either the mortality from phthisis was excessive or else some serious cause of error has operated to make it appear so. Three periods of especially great mortality are indicated from 1804 to 1832, the rate rising to nearly seventy in two of these, and falling to about forty-five in the intervals. Then follows a sudden and unexplained drop in the mortality curve to a point which is maintained with very little improvement during a long period of years, from 1838 to 1881. But it is evident that the periods of especial mortality, which still continue, show a decided tendency not to rise so high. From 1881 to the beginning of the present year the drop has been most striking, and coincides closely with that which is shown by the Massachusetts and Glasgow curves.

In the curve for England (Chart No. 3) the same conditions are manifest—namely, a fall from nearly thirty in the year 1853 to about fourteen in 1895, a reduction of over fifty per cent., corresponding closely to the percentage of reduction in Massachusetts and Glasgow, and greater than that in New York for the same period, but reaching a much lower point than in any of these places.

Chart No. 6 follows figures given by Dr. Farr.[3] From below upward the scale is the same as that of the other charts, but from left to right it is much compressed for economy of space. It shows, in periods of years, the mortality rate from phthisis in London from 1629 to 1888. These figures must be only approximate, since the first attempt to take a census of the population in England was made in 1801, and estimates for population before that time are said to have been made from the number of deaths; but at least this chart must give us some idea of the enormous mortality from phthisis in those times.[4] The figures have been quoted elsewhere to demonstrate that the introduction of vaccination influenced the mortality from diseases other than small-pox, since many persons who recovered from that disease were left peculiarly susceptible to phthisis; and so, with the reduction in the occurrence of the former, the mortality from the latter fell also. This fall is shown from 1801 to 1841, vaccination in England beginning in 1799. Other influences were undoubtedly also at work, for the years of greatest mortality, 1666 to 1679, were just after the great plague in 1665 and the great fire in 1666.

The effect of such influences on the mortality from phthisis is well shown on the chart for Paris (No. 4) by the curve during the war of 1870–71.

It may be noticed that the mortality for New York for 1804 and for 1812 was about the same as in London in 1801 to 1810.

Taken in connection with these enormous early mortalities, it is interesting to note that the disease which carried off, in the first year after their landing, fifty-one out of the one hundred Pilgrims who came to this country in the *Mayflower* in 1620, is thought to have been quick consumption.[1]

It can very well be believed that these mortalities must have been tremendous, when we realize that the average duration of life, as given by Dr. Wynne in his work on vital statistics, and calculated by Edward Mallet from the very accurate statistics of Geneva, which date from 1549, was in—

1550–1600	8	years	7	months	and	26	days.
1600–1700	13	"	3	"	"	16	"
1701–1750	29	"	7	"	"	13	"
1751–1800	31	"	3	"	"	5	"
1801–1813	40	"	8	"	"	10	"
1814–1833	45	"	0	"	"	29	"

Ireland is the only country, of those whose figures have been examined, to show a rising rate. This may be the result of lack of general prosperity and advancement in that country. In the city of Paris the mortality rate from phthisis is astonishingly great and has not been materially reduced.

In a "Summary of the Vital Statistics of the New England States for 1892" (p. 45), compiled by the secretaries of the several boards of health, the statement is made that "in those States which have had registration for several years, the mortality (from consumption) is found to be steadily diminishing."

Certain sources of fallacy must be taken into account in accepting these figures for phthisis. Newsholme says that "proper diagnosis of cases of phthisis is a slight cause of the reduced mortality, but not all, since the mortality from phthisis has diminished at all age groups, while the mortality from all respiratory diseases has increased only in the group under five years and in those over thirty-five years, and the chief mortality from phthisis is in the age groups from fifteen to fifty-five, while that from respiratory diseases is low during those years and greatest at extremes of life."[2] And the same author says, on p. 130: "There can be no question as to the great diminution of phthisis in this country [England], and that this is due to sanitary improvements."

"The mortality from 'phthisis' is diminished, at ages five to thirty-five, fifteen to twenty-eight per cent., whereas at all these ages the mortality from 'diseases of the lungs' remains comparatively stationary."[3]

The tendency to return deaths from phthisis hastened by influenza as due solely to the latter disease, has been noticed by Dr. Baker in Michigan. Dr. Tracy, registrar of vital statistics for New York City, says that he has investigated this source of error, and that, for New York City certainly, it is of little account.

Emigration of the sick has no doubt some share in the fall of the mortality rate from phthisis; probably greater effect in New York City than in a State or country as large as Massachusetts or England. Yet the majority of phthisical patients have not the opportunity for emigration, and very many who have emigrated come home to die. Dr. Tracy believes that emigration of the sick has had very little to do with

the fall in the mortality rate from phthisis in New York City.

Falsification of death certificates to avoid forfeiture of insurance has been alleged as a cause in the reduction of the mortality rate. Dr. Tracy informs me, however, that he has investigated this point also, and finds no evidence of a transference of mortality from phthisis to any other disease or class of diseases. Moreover, the reduced mortality from phthisis is mainly among women—a fact which gives rise to most interesting speculation—and the insured are mainly among men.

The assertion that "the apparent diminution in the death rate from tuberculosis is due to the facts that such reports [to health boards] tend to place a stigma upon the family and may invalidate insurance," is unimportant, since it is evident that the death rate has been falling steadily for many years.

Typhoid Fever.—Whatever doubt can be cast on the apparent significance of the mortality rates of other infectious diseases, the reduction of that of typhoid fever, I think, does not admit question. For wherever adequate water supplies and sewer systems have been introduced, there most striking changes have been shown in the mortality rate from typhoid fever.

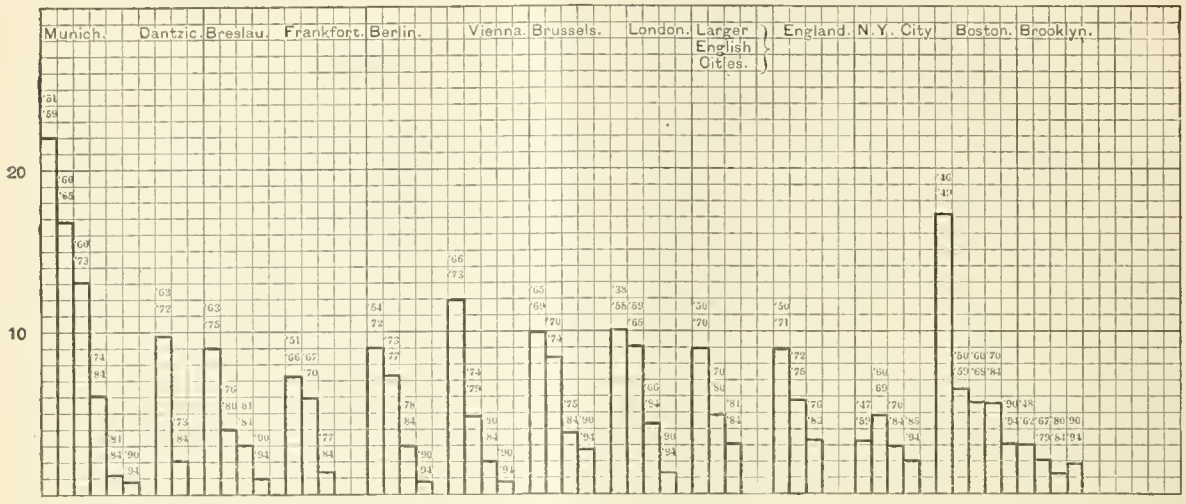

Chart No. 7.—Mortality Rates from Typhoid Fever.

The case for this disease may be allowed to rest on this chart alone (No. 7).[1] It shows the deaths from typhoid fever in each ten thousand inhabitants, over a very large part of the civilized world, before, during, and since the introduction of sewerage and water supply. These facts are emphasized in another way by this chart (No. 8),[1] which disproves the statement that reduction in the typhoid fever mortality rate is due to improved treatment alone.

A comparison of charts Nos. 1, 2, 3, and 4 presents in all of the curves a striking diminution in epidemic fluctuation and a highly encouraging tendency to fall toward a common point.

Conclusions.—It seems justifiable to draw the following conclusions from the facts presented: Good results are shown in many localities in the reduction of the mortality rate from diphtheria by sanitary measures alone, and we have reason to hope for still more striking and permanent effects from the introduction of the use of antitoxin.

With scarlet fever there is evident almost universally a quite marked tendency for a good many years to a steady decline in the mortality, with an absence of great epidemic fluctuations—a result which it is difficult to attribute to causes other than improved sanitary efforts, although the apparent tendency to cyclical movements in this disease should be borne in mind.

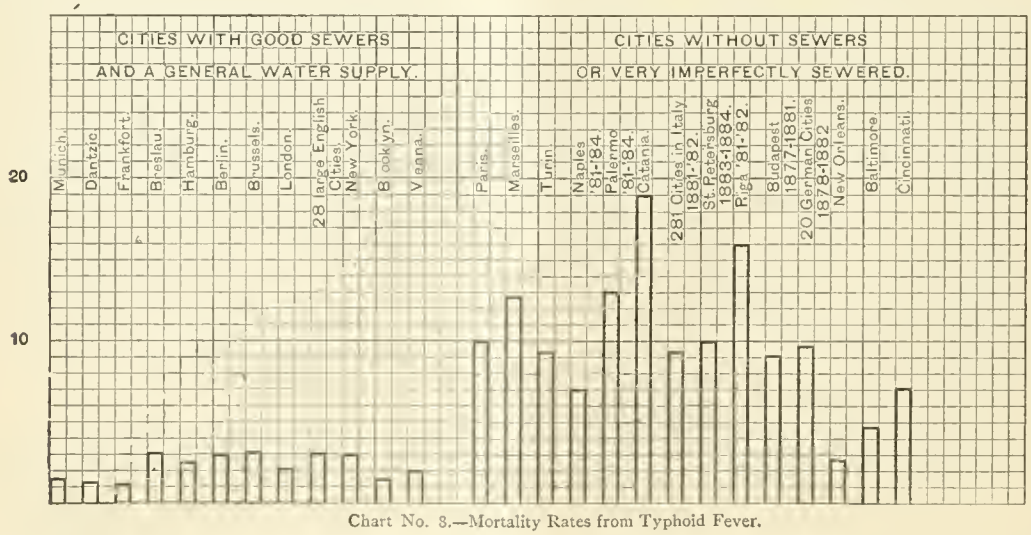

Chart No. 8.—Mortality Rates from Typhoid Fever.

In the case of consumption an immense decline in the mortality from the time of the earliest records is evident, and in late years also the decline has been rapid and marked. A great part of this later reduction is no doubt actual and permanent, but the effect

[1] *Ibid.*

of emigration of the sick and other sources of error have also somewhat to be taken into account.

The case for typhoid fever is unquestionably proved. While we must allow something for better results of treatment, it is certain that by far the greater part of the enormous reduction in its mortality rate is due to sanitary efforts alone.

THE DIET OF DYSPEPTICS.[1]

By MAX EINHORN, M.D.,

NEW YORK.

A few years ago I had the honor of reading a paper before this society, on "Dietetics in Diseases of the Stomach."[2] To-night I wish to discuss more fully a few points which are of eminently practical importance, and which I had at that time broached only superficially. The majority of dyspeptics, or of patients suffering from chronic digestive disorders, are affected with functional or nervous derangements. Most of these patients suffer either from loss of appetite or from gastralgia, sometimes from both, and hence take inappropriate and insufficient nourishment. Thus some live on small quantities of peptonized milk; others on artificial meat extracts (beef juice, liquid peptonoids, etc.). If these dyspeptics adhere strictly to this rigorous diet, they almost always depreciate more and more in health.

A marked fear of food is distinctly observed in all these cases. This symptom I would like to designate as "sitophobia" (fear of food). If the patients give in to this sitophobia — which frequently occurs—the dyspeptic symptoms increase more and more, even after the ingestion of small quantities of liquid and predigested foods. Soon varied symptoms of inanition manifest themselves, such as dryness in the throat, headache and dizziness, a feeling of decided weakness, intense anæmia, sometimes even pernicious anæmia.

Should we therefore be astonished if such patients, addicted to this wrong course of living, gradually waste away and finally succumb?

Either inanition itself, or complications arising in consequence of malnutrition, may easily bring on a fatal issue. As a whole, it is rather surprising how long these patients can live in spite of insufficient nutrition. This goes to show how tenaciously the organism clings to life; it learns to economize its expenditures and to subsist on scanty means. This is the only explanation why these invalids, who, after at first losing considerably in flesh, subsequently maintain their slight bodily weight and are able to lead a meagre existence.

Gentlemen, the number of such emaciated dyspeptics is not small, and every practitioner meets with a few of them every year.

I will now present a few points by means of which these cases may be recognized.

Generally speaking, the term dyspeptic signifies one who suffers from a chronic disorder of his digestive organs, without having, however, any organic affection.

We will have to determine, first, the presence of some protracted ailment (for one or several years); second, the absence of any organic disease (ulcer, stenosis) of the stomach or intestines. An examination of the gastric contents may be omitted in these cases, although the knowledge of the chemical condition of the gastric juice may sometimes be useful with regard to the treatment.

How shall we treat such dyspeptics? Medicaments are not of much value, or play only a subordinate part. The main factor lies in proper nourishment. These patients, who have abstained from most kinds of food for years, must now learn anew to eat. Their stomach and intestines very quickly adapt themselves to this new condition. First and above all, it is of importance to increase the quantity of nourishment; second, to provide a sufficient variety of foods. An ample but too one-sided diet (as a purely milk diet, or hot water and beef) is not suitable for a long period of time, for under this regimen there may be a partial lack of certain substances necessary for the welfare of the organism, and thus may be exerted a deleterious action upon the economy.

In order to improve nutrition, two articles of food, which hitherto have been often avoided by laymen as well as physicians, play an important part. I mean bread and butter. In my previous paper I have already hinted at this topic; I now take the liberty of again discussing it.

Bread forms one-third of the total amount of ingested food in health, and, besides having nutritive value, serves the purpose of increasing the flow of saliva during its mastication. It also creates an appetite for other food.

Butter not only improves the taste of various kinds of food, but is also in itself a nutriment of the greatest importance. The great number of calories which butter contains (one hundred grams give eight hundred and thirty-seven heat units, while the same amount of bread develops about two hundred and seventeen) shows this in the clearest manner. Another advantage which butter presents is that its volume is only about one-third that of bread. A patient taking about one-quarter of a pound of butter a day receives therewith more than one-half of the heat units required. This quantity of butter is, according to my experience, well borne by most of the patients.

I now take pleasure in presenting to you two cases, in which the main symptoms consisted principally of a deficient nutrition. By improving the latter the patients got well. These two cases I take at random from a large number of similar character.

Case I.—Miss G. M——, about twenty-six years old, suffered for the last five years continuously from marked dyspeptic symptoms. Severe gastralgia often appeared, which was frequently accompanied by vomiting. The appetite was not greatly decreased, but fearing the pains the patient abstained from most articles of food. Obstinate constipation was another of the troublesome symptoms present. The patient ran down very fast. She was treated by several eminent physicians, and as a last resort the ovaries were removed. Her ailments, however, persisted, and she steadily grew worse. When she first consulted me she reported that she had lost sixty pounds in weight. The patient was abed the greater part of the time, and lived exclusively on small amounts of peptonized milk and Wyeth's beef juice. A thorough examination of the patient did not reveal any organic disease of the digestive apparatus. A condition of enteroptosis was found, but this was not considered important. The patient was ordered to take more nourishment. She was at first placed (during the first week) on a fluid and semifluid diet: soon, however, the bill of fare was increased, and after about three or four weeks she partook of nearly all the plain and ordinary articles of food. During the first fortnight the patient continued to complain of manifold severe symptoms after meals, but soon her complaints grew less frequent and after a while entirely ceased. The patient was plentifully nourished in a methodical way (among other directions she was told to take one-quarter of a pound of butter a day), and she gained fifty pounds in weight in a period of five months. After that time she could be considered as restored to perfect health. She could

[1] Read December 21, 1897, before the section on general medicine of the New York Academy of Medicine.

[2] Einhorn, M.: New York Medical Record, June 24, 1893.

take long walks without fatigue, she rode a wheel, and attended to all her household duties.

Case II.—Mrs. Caroline A——, sixty-five years old, had suffered for the last four years, off and on, from dyspeptic symptoms. During the last five or six months her condition grew materially worse. The patient usually had severe pains after meals, and suffered from obstinate constipation, weakness, and insomnia. During this entire time she had been on a rigorous diet (beef juice, etc.), and had been treated with various medicaments: but under this treatment she had lost thirty-five pounds in weight. The physician in charge and also her relatives were of the opinion that she had a cancer. A thorough examination revealed only a downward displacement of the liver and stomach. The liver at first simulated a tumor, but on further examination it could be easily seen that the latter was the prolapsed liver, and not a neoplasm. The patient was told to partake of nourishment every three hours and was allowed certain articles of food which had been previously forbidden. At first zwieback, crackers, and gruels were permitted, besides a small quantity of scraped beef. Soon, however, the ordinary white bread, butter, eggs, and similar substances were added, and the patient began to gain in strength. (The wearing of an abdominal bandage was not advised, as the patient did not feel relieved when the lower part of her abdomen was supported with the hands when she was examined.) During a period of three weeks the patient gained eight pounds in weight, got rid of her dizzy spells, as well as her gastralgia, and could sleep much more comfortably. She is still under treatment, but her convalescence continues.

As nutrition plays the principal part in the treatment of these patients, it will not be amiss to give a few hints with regard to its management. To begin with, it does not appear advisable to permit patients who have abstained for a long while from the coarser varieties of food everything at once. This abrupt change may at times be the cause of various unpleasant symptoms; therefore it should be accomplished gradually. At first give, besides milk, gruels, and thickened soups, eggs beaten up in milk, etc. A few days later begin to add to this bill of fare zwieback or crackers with butter: then permit meat, the white of chicken and well-scraped beef: next, mashed potatoes: still later give wheaten bread, baked or boiled potatoes, soft-boiled or scrambled eggs, oysters: at last allow vegetables and fruits.

An essential point with regard to nutrition is punctuality in the taking of meals. In most of these cases, in which a gain in weight is of great importance, frequent meals (five or six daily) will be advisable. Although it does not appear advantageous to prescribe for the patient the quantities of the various foods in exact weight (grams or ounces)—as by so doing they are too easily reminded of their ability or inability to digest this or that quantity and not more—it is nevertheless of value to mention approximate figures by which they may be guided or below which they shall not go. Thus, for example, they may be told to eat as much as their neighbors at table, or that they shall take ten ounces of milk at this or that meal; or, as I frequently advise, that they shall consume one-quarter of a pound of butter a day. Emphasize those points which appear to be the most important, and leave the patient great liberty in all other particulars. We must strive to familiarize the patient with the idea that ample nourishment will strengthen his organs (including the stomach and intestines), and we must always endeavor to dispel the fear of food with which he is harassed.

For patients who are greatly run down and are confined to bed a nurse is advisable, who shall see that the physician's orders (with regard to food) are promptly carried out. Massage may certainly be used on and off as an adjuvant. For patients who are up and about, a nurse is unnecessary. In the latter instance it is important to see that the patient's time is properly occupied: by that I mean to say that the patients should lead a rational mode of living, and should work neither too much nor too little. With some patients (wealthy people having no vocation) we must try to give them something to do; while in the case of merchants whose business strain is too great, lawyers, and physicians, we should advise that sufficient leisure be taken. The points just mentioned serve in a high degree to render possible a healthy nutrition, for only a rational mode of living gives sufficient appetite for abundant food.

In cases in which the condition of the gastric juice is known there are still other special rules with regard to diet; for, as is well known to you, we should give abundant quantities of meat in hyperchlorhydria, while in hypochlorhydria and achylia gastrica the starchy substances (and vegetable food) should predominate.

The above suggestions, however, play the principal part in the treatment, and good results may be obtained often enough without analyzing the gastric contents.

Gentlemen, I have endeavored to give you in this paper a few practical hints with regard to the nourishment of most patients afflicted with chronic stomach troubles. If I have succeeded in convincing you that it is much more important to take care that such patients are sensibly nourished than to forbid them everything, I shall feel that my object has been accomplished.

20 East Sixty-Third Street.

THE POST-DIPHTHERITIC PALSY AND THE ANTITOXIN.

By JOSEPH McFARLAND, M.D.,

PROFESSOR OF PATHOLOGY AND BACTERIOLOGY IN THE MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA.

At this late hour, when every one ought to be informed upon it, one can scarcely undertake to write upon such a subject as this without feeling that an apology is necessary. Recent conversation with several otherwise well-informed physicians about the unfortunate outcome of some of their antitoxin-treated cases of diphtheria has convinced me, however, that there must still remain a large number of busy men in the profession who have not had time to think seriously upon the relation of the antitoxin to the palsies, and who need, in consequence, to have their thoughts properly directed. It is to them that I address this paper.

Of the various sequelæ of diphtheria, the occurrence of paralysis is most important. It is likely to come on in any case, and can be expected with equal frequency regardless of the therapeutic measures employed. More cases follow the use of antitoxin than any other mode of treatment, unless the remedy be prescribed early enough and in sufficient amount. This does not argue against the use of antitoxin, but for it.

The frequency with which diphtheria is followed by paralysis is said by Gowers to vary considerably in different epidemics and at different ages, and is variously estimated as occurring in from eight to sixty-six per cent. of all the cases. Sir Dyce Duckworth[1] finds it in from ten to twenty per cent. of all cases. It may not be an exaggeration of the truth to say that nearly one-fourth of all diphtheria patients who recover suffer from a more or less severe palsy in the course of the convalescence. The cases collected by

[1] British Medical Journal, April 4, 1896.

Landouzy indicate that the proportion of palsies is greater in adults than in children, and that the frequency of the trouble increases with each year of life.

The previous health of the individual seems to have nothing to do with the occurrence of the palsy. It does not more often occur in the weak than in the strong; it follows both mild and severe attacks, and occurs after diphtheria of the cutaneous surfaces as well as after the ordinary pharyngeal form.

As a rule, the primary disease is over before the palsy makes its appearance, but there are recorded exceptions in which the latter has come on earlier, sometimes on the second day. Quite a regular order of invasion is observed. It usually begins in the soft palate, and can be at first detected by a nasal quality of the voice and a tendency to regurgitate in drinking. The palsy may extend to the constrictor muscles of the pharynx, so that deglutition becomes embarrassed. A second very common seat of the disease is the eye, where the muscles of accommodation are affected. There may be strabismus and ptosis as well. In less common cases the palsy takes the form of a peripheral neuritis, which may affect a single limb or may be more widely spread, so that the limbs are found to be very weak when an attempt is made to stand upon them. In these "weaknesses" there may be loss of the knee jerk. The most important form that the palsy can take is found in connection with the heart. Heart failure and fatal syncope may come on at any time during the attack or during the convalescence. The multiple form of peripheral neuritis also occurs, and may be widespread and serious. It may begin with the ordinary affection of the throat and gradually extend to the limbs, where it is soon manifest by the muscular weakness, partial palsy, and loss of the tendon jerks. The palsies are most varied in character, and may affect all of the muscles except those of respiration, or may be limited to a few symmetrical or asymmetrical groups of muscles. When it is so widespread as to include nearly all of the muscles of the body, the case appears very desperate; in reality, however, only about one-half of these cases terminate fatally. Under ordinary conditions the cases progress slowly but favorably toward recovery.

I think it is the experience of most men that the majority of the cases of diphtheritic palsy seem to follow the severe attacks. Formerly "bad" cases meant those in which a large extent of membrane was formed in the throat. At present, however, the meaning of the term has changed somewhat, and, instead of the local conditions receiving so much attention, we devote ourselves to the constitutional aspects, and call only those cases "bad" in which there is a profound toxæmia. It is therefore a correct scientific statement to make when we say that the diphtheritic palsy follows the toxic cases, and is mild or severe according to the amount of toxin that is absorbed.

The amount of membrane that forms in the throat is no index of the amount of toxin that is to be absorbed, and therefore of the probability of the occurrence of palsy or of the severity of the palsy that is anticipated. The membrane is formed alike by distinctly toxic and mildly toxic bacilli, and its extent is dependent solely upon the vegetative powers of the bacillus. If it were always certain that a larger amount of toxin is absorbed from an extensive membrane, it would be very easy to gauge the cases and decide what the outcome would be.

It seems to be true, however, that when the bacillus causing the lesion is extremely virulent much more toxin can be absorbed from an insignificantly small patch of membrane than from the large patch produced by mildly virulent bacilli.

Whether, therefore, the case is one that appears serious or not has nothing to do with the real condition, which it is beyond the power of the diagnostician to tell. That a patient not very seriously ill may unexpectedly die is the common experience of many who have made good prognoses and subsequently lost their patients.

Without treatment, all cases of diphtheria are divisible into two classes: 1st, those that would recover spontaneously; 2d, those that would end in death.

Spontaneous recovery in diphtheria indicates that there has not been enough toxin absorbed to kill the patient.

There is only one scientific treatment for diphtheria: the use of antitoxin. If it could be determined exactly how much toxin a patient was absorbing, and therefore how much of it the antitoxin had to neutralize, the task of the physician would be very much simplified. As, however, there is no method of determining that at present, and as its determination would no doubt be attended with difficulty, it is only rational that all patients should be treated alike and in all cases sufficient of the remedy prescribed to neutralize more toxin than we are ever likely to encounter. This is in reality what every one who uses antitoxin judiciously does. In all of the directions accompanying the remedy it is explicitly stated that the dose should be large, and if necessary repeated several times. It is a pity that there ever should have been an accusation made that these instructions were originated for no other purpose than increasing the sales of the unfortunately but necessarily expensive remedy. Nothing could be more untrue. The dosage of the remedy has been worked out in the laboratory with the greatest expenditure of time and pains, and it is particularly worthy of note in this connection that the united experience of numerous entirely disinterested scientific bodies—such, for example, as the Pædiatric Society—has invariably led them to recommend larger doses than those suggested by the manufacturers.

In the treatment of a case of diphtheria according to the rules given for the administration of antitoxin, the physician injects as his first dose a quantity of the serum that is more than enough for the cure of a mild case, and probably enough for the cure of a bad case. In doing this, however, he makes no mistake, for the impossibility of estimating exactly what work the remedy has to do must not be forgotten. The one dose may be all that is necessary for the cure, or it may need to be repeated, sometimes may need to be repeated several times.

In either case, if the patient recovers, the physician has done one or the other of two things—either he has exactly neutralized the toxin in the child's body or he has done more than exactly neutralize it. In the latter case nothing of interest will be noted; in the former case the exact neutralization that would save life may not be enough to prevent the sequelæ of the disease, and that most common one—paralysis—will appear.

Need I add that in this illustration the antitoxin is not the cause of the palsy? Yet in a certain sense it is, for if the patient had died he would not have had palsy. It is because he lived that he has palsy; he lived because he received antitoxin, therefore he has palsy because he had antitoxin! This argument will surely make clear to every one that palsy is more common in diphtheria treated with antitoxin than in diphtheria treated without it. I would be glad to have the palsy if only I could be cured of the dreadful disease. The only suggestion for the avoidance of the palsy that I can give is to use more of the remedy and let the increase be given at the first dose.

I should feel that I owed my readers an apology if I had said this without offering them some experimental evidence of the truth of the argument.

When guinea-pigs are injected with diphtheria

toxin, they are differently affected, according to the quantity administered. A very small dose of toxin may produce no changes at all, depending upon the strength of the particular toxin employed. If the dose be a little larger the animal shows no change for a day or two; then it begins to show evidence of a constitutional disturbance, that lasts for three or four days, and then passes away and leaves it as well as ever. During the period of illness the animal seems to be much depressed, refuses to eat, sits with its fur puffed out, and as the result of its refusal to take food becomes thin and emaciated. If the dose be still larger, the day after the toxin is injected there is observed at the site of inoculation an œdematous swelling, which, according to the size of the injection and the virulence of the toxin, may be of the size of a pea or extend over most of the abdominal wall. The presence of such an œdema would in itself be sufficient to upset the health and happiness of the animal, but in addition to the swelling we find that the same constitutional depression that was observed in the former case is also present, and the animal sinks into a much more depressed condition than would be brought about by the local condition alone. Not infrequently the animals die from the combined effects of the toxin and inflammatory infiltration. The exact significance of the infiltration is a little in doubt; it seems to be true that the animals that are thus affected often do better than those receiving the same dose of toxin and showing no infiltration. If the dose of toxin be very large the animals of course always die—sometimes without the local lesion.

Guinea-pigs that receive both toxin and antitoxin can be divided into three classes: 1, those that are thoroughly protected; 2, those that are partly protected; and 3, those that are not at all protected. Two of these classes we can dismiss with a word. Those that are fully protected show no signs or symptoms at all; those that are not at all protected die. The interesting class is therefore the remaining one, whose members are protected, it is true, but so insufficiently that some signs of the disease can be observed in them. It is in this very group that we find the cases of palsy occurring.

The thousands of tests of diphtheria antitoxic serum that it has of recent years been my privilege to make have furnished me with an immense field of observation, the outcome of which has been the discovery that the guinea-pig cases form an exact parallel to the cases in human medicine. Among the animals of the interesting group mentioned, dozens of cases of typical palsy have occurred.

For the sake of those not informed upon the subject, I will briefly outline the method of testing antitoxins.

In order that the death of the animal shall be made absolutely certain if it is not protected, each guinea-pig used for the test is given ten times the least certainly fatal dose of the toxin as estimated by experiments upon a large number of animals. With this enormous quantity of toxin varying quantities of the antitoxin are mixed, and the strength of the remedy is estimated by observing which of the doses given is just sufficient to prevent the development of signs of disease.

It must be clear that in this work there is no uncertainty as to the amount of poison received by the animal; it is ten times as much as is necessary to kill it. Each one of these guinea-pigs is in exactly the same position as a child hopelessly poisoned with the disease and treated by antitoxin. To save one of these animals from death is really to snatch it from the grave, and to save the life of a child in the same condition is to do likewise. The children, like the guinea-pigs, are also divisible into three similar classes: 1st, those receiving enough antitoxin completely to protect them, so that they at once recover without further trouble; 2d, those that receive enough to save life, but not enough to prevent the further progress of the case and the development of sequelæ; 3d, those receiving altogether too little of the remedy and dying in consequence, as if no interference had been attempted by the physician. It is not in the cured or in the dead that the palsies occur, but in the ranks of the "barely saved," where they are very common.

The lesson that we should learn from this is, I think, clear. The antitoxin should be administered in doses sufficiently large to obviate all possibility of there being any unneutralized toxin remaining in the child's body to cause further damage. As the dosage cannot be accurately gauged, it will always be best to err on the side of too much rather than too little.

There is a second immensely important fact to bear in mind about the use of antitoxin—it must be prescribed early in the disease. All of the papers that have appeared upon the subject have, however, taken pains to inculcate this principle, so that its reiteration now is only going over old ground.

There is a scientific reason underlying this "must" also, for it is easily shown by experiment that the longer one waits after giving the toxin to animals before giving them the antitoxin, the less the likelihood of recovery becomes, until a time is reached when it is absolutely impossible to modify in any way the progress of the case to a fatal termination.

THE EDUCATION OF THE EPILEPTIC, WITH ESPECIAL REFERENCE TO THE VALUE OF INDUSTRIAL FARMS.[1]

By WILLIAM P. SPRATLING, M.D.,
MEDICAL SUPERINTENDENT, CRAIG COLONY, SONYEA, N. Y.

An American physician of note, delegated some years ago to attend a meeting of the British Medical Association, expressed, while speaking before the association, the following sentiment: "It seems hardly worth our while to attempt to put a five-thousand-dollar education into a five-hundred-dollar brain." The doctor's remarks were intended to apply to students of a certain class, and, while we may regard them as somewhat harsh and feel that they might have been clothed in softer language, candor compels us to admit that they contain more than a grain of homely truth, in so far as they apply not only to one class of students, but to a contingent of many classes to whom we are trying to give highly specialized knowledge far in advance of their needs or of their individual receptive and assimilative capacities fixed by the inexorable laws of nature.

And just here, for fear that I may be misunderstood, I make the unequivocal statement that I am not, to the extent of one jot or iota, opposed to the giving of an education that educates; an education that puts into an individual's possession an instrument fitted to his capacity to wield, and which instrument, if properly used, will tend to make him a producing and a self-supporting agent. This should be the end and aim of education. A man may not always be obliged to wield the club that is put into his hands, but it is there whenever he needs it. And that club with which his blows are to be struck must be fashioned according to his strength, his needs, his power to make it, to hold, and to use it.

A period of time measured by less than a generation just passed witnessed radical changes in our system of education, and the march of progress is just fairly begun. The newer educational methods have come as the logical result of a better knowledge of the human

[1] Read at a meeting of the National Conference of Charities and Corrections, held at Toronto, July 7 to 14, 1897.

forces as exemplified in psychology. We are trying to go hand in hand with nature in the teaching and acquisition of better things; trying to broaden and expand all that is good that nature provides, and to dwarf and subdue the evil.

While educational methods, in so far as they apply to teaching, have radically changed, and while the greatest good has come from the use of the newer methods, I believe we have not yet reached that high altitude of proper discrimination that teaches what is best for an individual to know. I do not think that we properly weigh and determine individual qualifications and needs; and from the vast amount of educational work to be done it is not likely, except in circumscribed cases, that we ever will.

The colony system in the care and treatment of epileptics forms an exception to the rule of limitations and makes a circumscribed case that it is my purpose to consider; and all that I may say hereafter in this paper on the education of the epileptic is intended to apply to him primarily as a colony resident, and afterward to him at large.

When it is realized that one person in every five hundred of the population is an epileptic, and when we further realize the more important fact that seventy-five per cent. of all cases of epilepsy begin under twenty years of age, and that not more than six or eight persons in every hundred who have the disease get well, and that unless especial pains be taken to correct the tendencies of the disease in early life, progressive mental and physical failure is sure to follow—we can appreciate the great value of the proper education for this class, especially when it carries with it the potent influences that serve so materially to stay the ravages of the disease. Not only, therefore, do we educate, but through the same agencies we ameliorate and cure. For no other class of dependants is it possible to do these two things at the same time.

In educating and training the epileptic it is well to bear constantly in mind the infrequency of the cure of the disease; and keeping that in mind, and understanding that he will always as an epileptic be an object of social and business distrust, and, if he remains uneducated and unimproved, an economic burden so far as the cost of his care is concerned, we can readily see that the kind of education he needs is one that will put, not complex algebraic formulas and a mass of ill-defined and useless knowledge of the dead languages and ancient history into his brain, that cannot be called into useful account through the ends of his fingers, but an education that puts an instrument into his hands that, wielded by him, will give him a practical result in the form of his daily bread.

I do not decry collegiate or scientific education. There are plenty who need it and can use it, but the epileptic is not among them. Brain processes for him must be simplified to the greatest possible degree, and before we begin to stimulate and educate them at all it is needful that they be strengthened and built up through the medium of an enlarged sphere of bodily action—an action daily and specifically employed in useful, helpful, saving manual labor.

How well the value of labor is understood at the great colony for epileptics at Bielefeld in Germany! I do not know when they learned the lesson, but that they know it and know it well is exemplified in the great diversity of industrial teaching that is going on there to-day in the name of charity. Julie Sutter, in "A Colony of Mercy," wrote of Bethel Colony: "The most striking feature of this colony of sick folk is its capacity for work; the place is a hive indeed, and as busy as a hive." What a revelation in charity methods! And every word of it is true, as I can testify from a two-weeks' residence at the colony, spent in intimate contact with the daily life of its inhabitants.

Going in and out among the houses at Bielefeld, you are confronted by a board sign nailed on the corner of a building. It reads "Workshop Street." You turn into this street and walk into the first house on the corner. It is the carpenter shop, and forty epileptics are daily employed here. In twelve months seven new houses, large enough to hold twenty persons each, were put up in the colony, and all the woodwork for them was done by these epileptic carpenters. They made besides an endless number and assortment of chairs, tables, and bedsteads, enough to supply the entire colony.

In one household a boy with a paralyzed arm blacked the boots of an entire household, holding the boots between his knees to accomplish the purpose. To learn how to do that was his education. It was as far as he could go, the best he could do; but, having learned it, he does it constantly and does it well. He earned a place in the industrial life of the colony. He could not have learned Greek or Latin, nor could he have become a teacher, a musician, a sculptor, or a painter; but there was something useful he could learn to do, and he learned it and did it.

On all sides and in every department there was the same display of systematic productive and useful energy; and what has it done for the dependants who are obliged to recognize and exert it? Just this: It has cured six times as many as are cured under any other system or form of treatment, and so greatly benefited from forty to sixty per cent. more under three or five years' treatment that many of them are able to go back to their homes and take up their former vocation.

Did labor alone do it all? you ask. No, not all; proper food, proper habits, proper environments helped, but labor was the keystone in the regenerative arch. Under its influence Bethel Colony produces the maximum of cures with the minimum of cost. And let us bear in mind the fact that there are no secret remedies, no all-healing drugs, no sacred charms, and that physiological and moral reasons in abundance can be adduced to explain fully the means that accomplish the end.

It has been our aim since the opening of the Craig Colony to profit by the lesson Bielefeld has learned so well; and, while the Craig Colony has been in existence for a comparatively short period of time, our experience has been such as to demand from us a warm indorsement of the Bielefeld methods.

Of the difficulties encountered I need not speak further than to state that they arose in consequence of having to deal with a rapidly increasing number of recruits, and under colony conditions not yet perfected in any department or particular.

The first one hundred and fifty patients came from county almshouses and poorhouses, where some of them had been forty years and where none of them had been accustomed to work.

And just here let me digress a moment, to say that my experience with them so far has caused a loss of faith in the so-called epileptic energy of legendary renown. I have not found that epileptics are any more ambitious to work than other people are, but there are exceptions, of course, that prove the rule. I am unable to understand how the belief in the so-called epileptic energy ever came into existence. It is against the simplest laws of nature, of physiology, to ascribe such a condition to a class of people who periodically and to an extreme degree expend every atom of energy there is in their bodies. The pent-up tide that often precedes the fit does not show itself in the way of energy to be spent in labor. It is rather an accumulation of the forces of the emotions, and of the psychic rather than the grosser material elements.

Of the two hundred and thirty epileptics admitted

into the Craig Colony since the opening, all of whom were admitted as not insane, not more than five per cent. of them, under the most liberal estimate, were capable of performing unaided any sort of useful labor. These are two reasons why this is true:

1st. The long standing of the disease and the consequent general deterioration.

2d. The lack of any kind of training after the disease began. Of the one hundred and forty-five subjects admitted prior to October 1, 1896, only one had been an epileptic for less than a year, while one hundred and twelve of that number had suffered from epilepsy for from five to forty years, and eleven for forty years and over. Sixty-three of the one hundred and forty-five had no occupation, while many to whom forms of occupation had been ascribed had been forced on account of the disease to count their vocation among the lost arts.

For the epileptic, therefore, we seek to accomplish two things:

1st. To cure him if possible.

2d. During the effort to cure him to educate and train him to useful and self-sustaining labor.

The means employed in the colony system to cure, to educate intellectually, morally, and industrially, and to teach self-support, are so intimately interwoven that they must be considered as one and all at the same time.

When they enter the colony the patients' education is begun along two lines—one to give them a common-school education; the other to put a means in their possession whereby they can become producers as well as consumers, and at the same time become themselves the effective agent in the application of a remedy of untold value in the treatment of their disease. The first is necessary by virtue of the fact that educational advantages are denied to epileptics in the common schools, and the character of the disease is such that the majority of them will always suffer from it and be isolated from home ties; and the ability to communicate with friends is a simple pleasure that should not be denied them.

The younger patients are sent to school two and one-half hours a day, and besides being taught to read and write they are taught many other simple things, the entire trend of the methods pursued being toward the awakening and development of the powers of observation and the cultivation of the motor activities, combined with only a modicum of study directed solely to the stimulation and growth of the higher intellectual faculties. Modelling in clay, studying the forms and sizes of figures—in fact, kindergarten work of all grades is of value to them and should have a place in their education.

Nature studies, too, should have a place in their curriculum. Their knowledge of nature, of plants, shrubs, and flowers, and of birds and insects is meagre to a marked degree. Some of the younger patients who have come to us from the great cities had never seen a pig, did not know that milk comes from cows, and could not tell a carrot from a mullein stalk. The birds, their haunts and habits, and the trees of the forest were as inanimate objects to them, while in reality these things are all full of beauty and perpetual interest to the eye that sees and to the mind that has some knowledge of the wonders of nature.

Nature study is receiving much attention at Cornell University, and the following is a brief description sent out from that university as to what nature study means:

"It is seeing the things which one looks at and the drawing of proper conclusions from what one sees. Nature study is not the study of a science, as of botany, entomology, geology, and the like. That is, it takes the things at hand and endeavors to understand them without reference to the systematic order of relation of the objects. It is wholly unsystematic and informal, the same as the objects are which one sees. It is entirely divorced from definitions or from explanations in books. It is therefore supremely natural. It simply trains the eye and the mind to see and to comprehend the common things of life; and the result is not directly the acquirement of science, but the establishment of a living sympathy with everything that there is. The proper objects of nature study are the things which one oftenest meets. To-day it is a stone: to-morrow a twig, a bird, an insect, a leaf, a flower."

How simple! you may be tempted to exclaim. So it is; and yet it is just what these defectives need and about which they know so little. It is the beginning of knowledge, the very first lessons in the training of the powers of observation. It leads to reasoning and creates a desire to investigate.

Next in order in the education of the young epileptic comes the use of all forms of industrial training, and the value of an institution for the care and treatment of epileptics may be measured largely in proportion to its ability to furnish the means for the accomplishment of these purposes. Such an institution should possess no lack of broad and fertile acres where the minimum expenditure of labor will produce the greatest yield.

Not only is outdoor life best for the epileptic, but his efforts well directed in the garden and on the farm will go farther than in any other direction toward producing his support. Agricultural work for him has a double value, and our experience has been that just in proportion to the increasing number of hours spent in active out-of-door labor, there has been a corresponding decrease in the number and severity of seizures, and that the good effects are most marked when individual interest shown in the work is greatest.

However unscientific the theory may be—which I do not concede to be the case at all, but which cannot be discussed here—it is my firm conviction that energy that would be illegitimately expended in a convulsion may be made to expend itself gradually through the medium of legitimate muscular exercise. I might cite a score of cases in support of this belief, and one of them is of such interest that I will briefly mention it.

V. S——, a young man, twenty-six years old, was admitted to the colony, February 5, 1896. He had been an epileptic eighteen years. Twice he had been under treatment in State hospitals, and was discharged from them both times as a hopeless case. He had no occupation, could do nothing, and when admitted his attacks averaged from three to five in twenty-four hours; and that had been his record for five years. He was extremely emaciated, tottered in his walk, and had to be assisted to his meals by two persons. We got him out of doors as soon as the weather was mild enough, and when potato planting commenced he was sent to the field and made to take part in the work. He began immediately to acquire an appetite, gained in weight, had fewer attacks, and during the three months that followed the change that was wrought in his condition in every respect was little short of marvellous. During the first month at the colony he had 110 seizures: second, 98; third, 13; fourth, 0; fifth, 1, and this was due to the excitement incident upon a visit to him of relatives who took him from the colony over night; and for twelve months he has not had a seizure. He has learned the printer's trade and is now doing most of the printing-work of the colony.

Next to farm and garden work the greatest value for the epileptic lies in the forms of industry that call for the systematic and measured expenditure of muscular force indoors. Such work includes carpentry, ironwork, shoe and mattress making, and so on. A course in elementary woodwork, such as the Sloyd system

provides, is of the greatest value. Under this system the eye, the faculties of the mind, and the muscular system are conjointly exercised, educated, and strengthened. From the initial step of the work in wood, a simple straight groove cut in a short board, there grows out the ability to carve, turn, and make woodenware and furniture of all kinds.

Most boys have a natural fondness for tools, and the Sloyd system fixes their use in a systematic and useful way. The epileptic is fertile in irregular and ineo-ordinate muscular movements, and one of the most valuable features of the Sloyd system is in the toning down and drilling into purposeful movements the entire muscular apparatus.

We are on the point of introducing the system at the colony for a class of twenty boys. I might go on to an indefinite length specifying the forms of labor suitable and valuable for epileptics to engage in, but it is unnecessary. The main thing is labor—labor that demands a real use of muscular force; labor that is systematically performed; labor that opens the pores of the skin, quickens the circulation, brightens the eye, and brings about a healthful physiological fatigue; labor that has a place in the world of economics; labor that conquers all things.

As further exemplifying the value of labor, I had taken from the records of the colony the histories of eight patients who under its influence have been benefited at the colony, almost to the extent that the case cited above had, and, singularly enough, they are all men and boys, no girls or women among them.

For obvious reasons the employment of the female patients at the colony up to the present time has not been practicable, further than that they have weeded in the garden and done a little play work about the lawns and in the houses. But what is good for one sex is good, properly modified, for the other. Slightly different means may be just as successfully used to accomplish this end, and as soon as possible we shall carry out such a policy at the colony.

I need say nothing of the difficulties to be overcome in the carrying out of these plans. I have spoken only of the excellence and value of the plans in operation. It is not easy to do, and it is only through the application of the same persistent force that a falling raindrop has when it wears a stone away that anything can be accomplished.

Of the value of medicines and proper diet, I likewise have not spoken. Both have a place high up on the list of remedial and curative agencies. As triple forces, medicine, diet, and labor, under judicious, continuous, and discriminate use, are destined to accomplish more toward relieving the distress of this great afflicted class than we have sufficient wisdom to understand to-day.

Gastric Ulcer.—Three methods of operating for gastric ulcer must be considered: (1) Resection, which is the most dangerous method and not very satisfactory, but must be performed when the case is considered to be one of carcinoma: (2) pyloroplasty, which is a more simple method, but can be carried out only when the gastric and duodenal walls are soft; and (3) gastro-enterostomy, which also gives good results, though sometimes the contents of the stomach penetrate into the ascending limb of the jejunum, and Professor Mikulicz therefore recommends that a second anastomosis should be made between the two loops. Speaking of the indications, he says that in cases of adhesion of the stomach to adjacent viscera, an operation is necessary to relieve the pain and the adhesions must be separated. In cases of perforation immediate laparotomy is essential. When the patient cannot take an anæsthetic local anæsthesia must be used.—Professor von Leube.

AN OLD REMEDY FOR DIABETES MELLITUS.

By REYNOLD W. WILCOX, M.D., LL.D.,

NEW YORK.

PROFESSOR OF MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO ST. MARK'S HOSPITAL.

About ten years ago a drug was introduced as a new acquisition to our materia medica which at that time attracted considerable attention. Inasmuch as its active principle had not been determined and its chemistry was still unsettled, in spite of some favorable reports it did not receive the thorough investigation which is now possible, and it gradually fell into disuse. Many of the reports demonstrated its utility, while others recorded but negative results. Besides, there was great discrepancy in dosage, as recorded by several observers. It is worthy of remark that in no instance were any untoward symptoms observed. My own experience, although limited, convinced me that the drug was capable of accomplishing distinctly beneficial results, and that of some failures to obtain these results the cause might be sought for in our rather scanty knowledge of the morbid processes going on, of which persistent glycosuria was a prominent symptom.

During the decade just passed the unknown of diabetic pathology has been considerably lessened, and to-day we do not permit the view that the present unknown is long to remain unknowable. At that time I believed jambul to be a new drug. My reading since that time has taught me that it is a re-discovery. As we read Kaviratna's excellent translation in the "Charaka-Samhitā," which traces its origin to the time of Harun and Mansur (A.D. 775), we find jambul or jamvu (jambu), as the original has it, used in gruel as an astringent (p. 17), the leaves to relieve vomiting (p. 39), and that the bark alters the color of the fæces and reduces the secretion of urine (p. 41). This was a pretty closely reached opinion based upon empiricism, for glycosuria was not known until the time of Thomas Willis in the seventeenth century, who ascertained that sugar was present in the urine of patients suffering from polyuria and emaciation.

So far as ascertained, jambu, or jambul, as we prefer to name it, has been in uninterrupted use in India for twelve centuries. Ten years ago we had not advanced much further. We used the powdered seeds, and, tentatively, since the dose was undetermined, in undoubtedly too small quantities. For all that more extended experience led me to increase the dose, yet never was the dosage administered in an adequate amount. With the larger dose more and more obstinate constipation supervened, which necessitated the morning administration of a saline laxative. The results were good, still failures ensued. Some observers recorded that the sugar reappeared as soon as the remedy was discontinued.

To-day we stand in a decidedly different position. The last word on the subject of diabetes is to be found in the Medical Record of recent date, where we learn from Pavy that the serious fault is in the villi of the intestine. To be sure, the future may have in store for us that we shall ascertain that the trouble is a nervous condition acting upon the vessels of the intestine, but at this writing we know that in the alimentary tract the carbohydrates are so changed that little or no (practically no) sugar gets into the portal vein. Further, any sugar which finds its way into the portal vein, or in any way gets into the general circulation, is rapidly and completely eliminated by the kidneys. It is undoubted that the carbohydrates are changed into fat, for almost as much fat is found in the lacteals after ingestion of carbohydrates as after ingestion of fatty food. So long then as we can prevent sugar from finding its way into the

portal circulation, just so long can we prevent sugar elimination by the kidneys and the various renal degenerations resulting from the same. Coincidently with the presence of sugar in the urine we find that the power of assimilation in the intestine is weakened.

The first patient to whom I administered jambul presented such a brilliant result that a recital of his history is of interest.

A merchant of forty-two years of age had suffered from loss of flesh, progressive weakness, and considerable thirst for the past six months. When he consulted me on April 25, 1886, he was accustomed to rise four or five times each night to void urine. His appetite had markedly increased, and that, when taken into consideration with his loss of flesh, had attracted his attention. He was still in fair flesh, but a considerable number of wrinkles on his face showed that he had emaciated. A careful physical examination detected nothing beyond flabby muscles, a pulse rate of 90, and a high-pitched, shortened first sound of the heart. The urinary examination showed that he was passing daily eighty-six ounces of urine of a specific gravity of 1.038, which contained five and one-quarter per cent. of sugar. A moderate regulation of diet was ordered, namely, prohibition of foods containing a large starch percentage, but not excluding bread if toasted. On May 9th, the amount was reduced to seventy-two ounces and the sugar to four per cent. Jambul in five-grain doses of the powdered seeds was given after each meal. On the 16th, the amount was reduced to sixty-three ounces, the specific gravity to 1.028, and the quantity of sugar to two and one-half per cent. On the 20th, the quantity was fifty-two ounces, and sugar percentage one and one-quarter. The dose of jambul was now doubled. On July 17th, the amount was slightly lessened (fifty ounces), but the sugar excretion had fallen to one-fourth of one per cent. Since the constipation was the chief complaint, a half-bottle of Hathorn water was given on rising. The strength had somewhat increased, the muscles were firmer, and the first sound of the heart was nearly normal. The patient rose but once at night, and that rather from force of habit. On August 11th, the quantity was forty-eight ounces, the specific gravity 1.021, and no sugar was found. On September 21st, substantially the same report was presented. The appetite had now become normal; jambul in five-grain doses was continued to the end of the year. For the three succeeding years the drug was used only occasionally, and the patient remained in good health.

On November 7, 1890, the patient consulted me for a rather severe broncho-pneumonia which had confined him to his bed for two days. This was recovered from in fifteen days, the low temperature (99° to 100.5° F.) being the only unusual symptom. On the 10th, three-quarters of one per cent. of sugar was found. This was reduced to one-quarter of one per cent., by the 14th, under ten-grain doses of jambul thrice daily. No sugar was found on the 18th or 22d, but the drug was continued until December 6th.

Examinations on January 13 and 28, 1891, developed nothing abnormal, excepting that upon both days the quantity was above fifty ounces (fifty-six and fifty-one). On December 18th of that year, a careful examination detected no sugar. During 1892, jambul was used occasionally for a few days at a time. Since that year—that is, for the past five years—I have seen this patient at frequent intervals, but have never prescribed for him. He lives upon his ordinary diet, and always reports that he feels well. He is able to attend to his business, and is unwilling to believe that he has ever suffered from any serious disease.

In this instance the outcome was all that could have been desired, and this may be cited as one of the many cases on record in which, as Van Noorden says, such good results have been obtained with jambul that they cannot be ignored.

In arriving at an opinion as to the mode of the action of the drug, we have certain facts upon which we may rely. The analysis of Lascelles-Scott, as reported in the "Pharmacology of the Newer Materia Medica," 1892, showed that, while a certain quantity of diastasic matter (freshly made but rather weak malt extract) converted 44.8 per cent. of starch (amount employed being fifty grains) into sugar in fifty minutes, normally with the same materials and in the same time 19.6 per cent. was so converted when fifteen grains of powdered jambul was also present, and only 12.6 per cent. when twenty-five grains of the seeds was present.

In the *Lancet* for 1889 the observations of von Mehring and Graser are recorded. They first induced an artificial diabetes in dogs by the administration of phloridzin and later gave jambul. The latter drug promptly reduced the amount of sugar excreted to one-sixth or one-tenth of its former amount.

From these observations it is evident that we need not invoke the explanation advanced by Morse in the *Maryland Medical Journal* for October, 1887, where he claims that the drug increases vasomotor and reflex functions of the spinal cord, producing a general rise of blood pressure, especially in the renal arteries, to account for the relief of distressing symptoms and returning health and strength. Nor, indeed, are we surprised that in the East it is believed to possess the power of producing a rapid and in many instances a permanent cure.

The source of the drug is the bark and seeds of the Syzygium Jambolanum (De Candolle) or Eugenia Jambolana (Lamarck). This is one of the Myrtaceæ, to which the common names of rose apple and Java plum have been applied. The tree is found in tropical Asia and the neighboring islands. Vix, in the *Therapeutische Monatshefte* for April, 1893, prefers the rind from which to obtain his preparations, on the score of expense. Personally I am in accord with Stevenson, who regards the seeds as more powerful; the preparations made from them are the more serviceable and only certain agents for administration. Probably all parts of the tree which are used in medicine are astringent, from the contained tannic or gallic acid.

The analysis of the seeds made by Elborne in 1888 is probably the most accurate. He found:

Insoluble residue	83.75 per cent.
Moisture	10 "
Coloring matter	2.7 "
Albumin	1.25 "
Gallic acid	1.65 "
Resin	0.3 "
Chlorophyll	0.27 "
Essential oil	Trace.

So far, analysis leads us to believe that the bark, and probably the seeds as well, contain an alkaloid or glucoside. Gerrard has isolated a white crystalline substance possessing the formula $C_{10}H_{15}NO_3$, which is tasteless, soluble in ether, alcohol, and chloroform, but insoluble in cold and slightly so in warm water. It is quite likely that this presumably active principle exists in the resin and in connection with a special acid. We may justly expect that an analysis made at the present time, making use of more modern methods, would establish the chemistry of the drug on a substantial basis.

As for the dose, Stevenson administered from five to ten grains of the powdered seeds. Britto[1] gives one drachm of the powder or of the fluid extract thrice daily, stating that an ounce of the powdered seeds may give rise to nausea and depression. Rosenblatt and Zevasker used both the powder and fluid extract.

[1] Indian Medical Record, July 18, 1892.

In the early days of the study of this drug I made use of the powdered seeds; the fluid extracts proved to be disappointing, perhaps owing to failure to possess reliable methods of extraction. As the demand for the drug became greater, I discovered that it was apparently less reliable, and careful investigation showed that a considerable amount of Indian real estate was being purchased as jambul. These uncertainties were done away with, to a very great extent, by procuring the seeds and comminuting them as required.

The earlier clinical reports, as found in the *Practitioner*, *Lancet*, *British Medical Journal*, and *Bulletin Général de Thérapeutique*, were discriminating, and in the main favorable to the drug; yet it was felt that both its chemistry and pharmacy required much revision.

Recently my attention has been called to a preparation which promises to yield the beneficial effect of jambul. The formula is:

℞ Jambul	50
Buckthorn bark	20
Celery	5
Aromatics (Paraguay tea)	25

The buckthorn bark is introduced to counteract the constipating effects of the jambul, to which allusion has already been made. The excipient, Paraguay tea, contains a very satisfactory percentage of caffeine, which is undoubtedly useful for the weak hearts so generally met with in diabetic subjects. Altogether it is not a disagreeable preparation when administered in from two to four drachm doses every four hours. Thus far the results have been eminently satisfactory. If it should be found that the questions of pharmacy have been solved in this preparation, we can accept without reserve the dictum of Levaschev, of Kazan, who believes that jambul is superior to all other known remedies in the treatment of diabetes, according to the *American Medico-Surgical Bulletin*, September, 1897.

749 Madison Avenue.

Progress of Medical Science.

Leucin and Tyrosin in the Urine of a Case of Erysipelas.—For many years the presence of leucin and tyrosin in the urine has been looked upon as distinctive of acute yellow atrophy of the liver and of phosphorus poisoning, although cases of each of these disorders have been reported in which neither substance was present. Both substances further have been found in conjunction with diseases other than those of the liver; for instance, typhoid fever, smallpox, epilepsy, leukæmia, and hydrophobia. Some authorities have even maintained that leucin and tyrosin are normal constituents of the liver. The microscopic appearance of these substances is alone not sufficiently characteristic, so that a reliable conclusion requires, in addition, confirmation by chemic tests. An interesting case is reported by Kirkbride (*Centralblatt für innere Medicin*, 1897, No. 41, p. 1,057), in which leucin and tyrosin were demonstrated both microscopically and chemically in the urine of a girl, eighteen years old, who was passing through an attack of facial erysipelas. The urine examined on the ninth day of the disease exhibited characteristic spheres of leucin and crystals of tyrosin. The secretion was of acid reaction and failed to precipitate uric acid on addition of hydrochloric acid. To isolate the leucin and tyrosin the sediment was separated by means of centrifugation, then extracted with hot alcohol, and filtered. The filtrate, evaporated almost to dryness and permitted to stand until crystallization had taken place, yielded numerous layers of leucin crystals, displaying a deep yellow color. The alcoholic residue was digested with hydrated copper oxide in aqueous solution and the resulting precipitate filtered. The resulting solution evaporated to the point of crystallization contained small pale blue granules, containing nitrogen and soluble in water with difficulty. The precipitate upon the filter was treated with hot potassium sulphide, and the resulting filtrate evaporated and extracted with alcohol. In the residue of the alcoholic extract the leucin crystallized out in macroscopically visible granules, which responded to further chemical tests for leucin. The tyrosin was demonstrated by treating the residue left upon the filter after extraction with alcohol with hot water, to which ammonia had been added, and evaporating the solution to the point of crystallization. The crystals, which appeared as granules and sheaves, formed a red precipitate when dissolved in water, heated with mercuric nitrate, and finally boiled.

The Treatment of Gout.—What is gout? Must we believe with Professor Bouchard that it is a disease caused by scant nutrition, or with Lecorche that it is a trouble due to exaggerated nutrition? Or shall we think with Murchison that it results from hepatic insufficiency, or again explain all by uræmia as Garrod does, or think with Sir Dyce Duckworth that it is a question of bulbar trophoneurosis? Shall we consider it a proteiform dystrophy which may bring into play one or the other of these processes? This opinion would perhaps be the wisest. In any case it does not carry with it an absolute or doctrinal idea, and consequently one which results in theoretical treatment which is not even symptomatic. A useful mode of treatment ought to be symptomatic when gout is involved. The sufferer from gout demands relief, that the articulations may be reduced, that he may eject uric acid and urates instead of carrying them into the tissues and especially into the articulations. What medication can fulfil this complex requirement? Is it salicylates, antipyrin, iodine, quinine, lithia, the alkalies, or what? Each of these substances has its indications and its line of action, we might say, but no one alone can respond to all indications. There is nevertheless an old remedy that produces these various effects: it is colchicum. Unfortunately colchicum contains certain acrid substances which act as an emetic. It quite frequently cannot be tolerated. Some years since Lartigue, a member of the Academy of Medicine, tried to do away with these secondary effects while preserving to the remedy its peculiar activity. He prepared small pills, in which he put five centigrams of extract of colchicum deprived of its nauseous elements. He added a small dose of sulphate of quinine and digitalis, and enveloped the whole in a resinous substance. This remedy he employed upon himself during the rest of his life without feeling any disagreeable effects, and was entirely relieved of his sufferings from gout. The pills should be made of absolutely pure extract of colchicum, and covered with some resinous substance, and then again with thin goldleaf. In this way they traverse the stomach intact and dissolve only in the intestine. The colchicum liberated here easily penetrates to the tissues, modifies nutrition, acts on the trophic articular nervous system, and perhaps directly on the articulations. It calms the pain, causes the attack to cease, and reduces the size of the articulations. The patient should commence with two pills, one eight hours after the other. After each he is to eat something or drink some hot infusion. Then it will be necessary to regulate treatment in the following manner: Two pills in the morning, one at midday, and one at dinner. The following day he can take two pills on retiring, and

four during the following day, taking one when he retires. In a chronic case it will be well to prescribe one pill daily at meals for five days, then nothing for ten days, then five pills daily for five days, etc. It is often useful to complete the action of the colchicum by giving an alkaline powder in the interval. One of the best contains soda, lithia, and magnesia, combined with carbonic, citric, and benzoic acids. By this means the solution and elimination of uric acid and the urates are said to be effected.—*La Médecine*, October 2, 1897.

Therapeutic Hints.

Syphilitic Laryngitis.—

℞ Hydrarg. chlor. corros. ..... gr. i.
Potass. iodidi..... ʒ ij. to ʒ iv.
Syr. sarsaparillæ comp. ..... ʒ iss.
Aq. ..... q.s. ad ʒ iij.
M. S. ʒ i. twice daily after meals.

—Stevens.

Acute Catarrhal Bronchitis.—

℞ Potass. citrat..... ʒ ss.
Apomorphinæ hydrochlor..... gr. i.
Syr. ipecacuanhæ ..... ʒ ss.
Succi limonis..... ʒ ij.
Syr. simplicis .....q.s. ad ʒ iv.
M. S. ʒ ss. in water every three hours.

—Wood.

Or:

℞ Vini ipecacuanhæ ..... ʒ ij.
Liq. potass. citrat..... ʒ iv.
Tr. opii camph.,
Syr. acaciæ.....āā ʒ i.

Insomnia.—Nature's plan for curing insomnia is to limit the supply of oxygen to the blood. The cat and dog bury their noses in some soft hollow in their hair or fur; birds put their heads under their wings, and soon fall asleep. Those suffering from insomnia should cover their heads with the bedclothes, and breathe and rebreathe only the respired air. When drowsiness is produced sleep quickly follows, and the bed covering may be pushed aside and as much fresh air obtained as is needed.—*Indian Lancet.*

The scientific basis for the above idea no doubt lies in the fact that a certain degree of cerebral anæmia is requisite for the production of sleep. It is well known experimentally that dogs deprived of their normal cerebral blood supply by ligation of the carotid and vertebral arteries are afflicted with an intense drowsiness, so great that they readily fall asleep under most adverse conditions and are aroused with much difficulty. Practically there might be some difficulty in carrying out the plan suggested, but theoretically the soundness of the idea cannot be questioned.—*Yale Medical Journal.*

Tinnitus Aurium. Dr. Aubert suggests in *La Médecine Moderne* a means of avoiding the ringing in the ears caused by quinine. The addition of five milligrams of atropine daily to preparations of quinine will suffice to prevent any inconvenience.

The Treatment of Exophthalmic Goitre and Other Vasomotor Ataxias with Preparations of the Thymus Gland and of the Adrenals.—From the clinical observations, including sphygmographic tracings made in the various cases I have thus far studied, I conclude that thymus extract will in many cases of exophthalmic goitre improve nutrition, mitigate nervous disturbances, reduce exophthalmos, greatly reduce goitre, and moderately quiet the heart and restore vascular tone, completely accomplishing this in milder cases; while adrenal extract seems to have greater influence upon the circulation and less effect upon the thyroid and ocular symptoms. I am making studies upon the blood and secretions, which are not sufficiently advanced for publication. I do not believe that either of these remedies or any other remedy removes the fundamental, constitutional, idiosyncratic instability of the toxic mechanism of the circulation; but I do believe that they are competent in the one case—thymus—chiefly by an antitoxic action to counteract the exciting influences, and in the other case—adrenal—chiefly by opposing action upon the circulation to neutralize the effect of those influences. Probably both share both these actions in some degree, and I should expect the best results to follow their combined administration.—Dr. Solis-Cohen, *Journal of the American Medical Association*, July 10th.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 1, 1898.

THE REPORT OF THE RUSSIAN PLAGUE COMMISSION.

OF the various governments which sent scientific commissions to study the epidemic of the plague in India last year, there was none which was more directly and immediately interested in the practical results of such an inquiry than the Russian. Extensive epidemics of cholera and influenza have within recent years invaded Russia in Europe from her Central Asian possessions, and the sanitary authorities have been more or less concerned lest the Indian pest advance northward and enter Europe through these same channels. There is also a constant menace of a lighting up of some of the endemic foci of the disease which are known to exist in Asia and of an independent epidemic invasion from such source. We may therefore well understand the lively interest with which the report of this commission has been received by medical men throughout Russia, and especially by those in the south who would be called upon to resist the first approaches of the disease in case of possible invasion. The report, which was read at one of the section meetings of the International Congress and again at a meeting of the Kiev Medical Society, is published in the *Russki Arkhiv* of October 31, 1897.

The commission consisted of Professor Vysokovich and his assistant, Dr Zabolotny; Dr. Redrov, the third member, was ordered to Poonah almost immediately upon his arrival in Bombay, and so took no part in the main labors of the commission. The epidemic which began in September reached its height in January and had already begun to decline, the panic having for the most part subsided when the Russians arrived in the city about the end of February. By the beginning of June the epidemic was practically at an end, new cases for study being by that time found with some difficulty, and when the commission left Bombay, on July 2d, all the emergency hospitals were closed with the exception of two, which were for the reception and care of convalescents. The commission had therefore only about three months in which to study the affection. The authorities received them very kindly and placed four hospitals at their disposal, only two of which they were able to use, namely the Grand Road and the Charni Road Hospitals.

The report of the Russian commission is an excellent monograph on the plague as regards chiefly its clinical, etiological, bacteriological, and therapeutical features, but it contains few facts that were not already well known to those conversant with the results of earlier investigations in Bombay and during the previous epidemics in Hong Kong and Amoy. Dr. Vysokovich admits that the plague is a most formidable disease when once it has fastened its clutches on any one, native or European, but he regards it as comparatively easy of control by reason of the slight resisting powers of its bacillus, which cannot live long in water and perishes when dried. It is an "indoor" germ, the contagion being carried in clothing and other fomites or transmitted by direct contact. The members of the commission could not satisfy themselves as to the truth or otherwise of the popular belief that the disease is spread by rats and in grain. If rats are not instrumental in transporting the disease, the plague can be very certainly prevented from entering a country by means of an effective quarantine, but this is a difficult matter in the case of a long artificial frontier line, not formed by wide rivers or high mountains with narrow passes. The measures best suited for the crushing out of an epidemic already established are therefore of importance. Those which were the most successful in Bombay consisted in removing the sick at once to a hospital and the well from the infected house to quarantine for eight or ten days, the house where the case occurred being thoroughly disinfected before its former inmates were allowed to re-enter it. The clothing and other articles which have been in contact with the sick should be disinfected by dry heat, or better, if of little value, burned up. If all people were intelligent and reasonable, an epidemic of plague could be readily controlled by simple measures such as these, but experience in many parts of the world has shown the difficulty and danger of dealing in this way with an ignorant populace; hence the necessity of quarantine.

Naturally the experiments in orrhotherapy made by Haffkine and Yersin are referred to at some length. In the experience of the Russian commission neither Yersin's nor Haffkine's serum conferred any lasting immunity, a dose of ten cubic centimetres of the former or five cubic centimetres of the latter making a monkey immune for only ten days or two weeks. The injection of a fresh agar culture, kept at a temperature of 60° C. for one hour, produced immunity more slowly, but the protection so obtained was more lasting. The curative effects of the serum were better, yet they could hardly be regarded as entirely satisfactory when it is stated that forty per cent. of the cases treated by Yersin's serum terminated fatally. Apparently, therefore, we cannot yet rely upon serum treatment to repress an epidemic of the plague, and so we must still look to the much abused quarantine to preserve a country threatened with a visitation of this reviving enemy of the human race.

The Laurens County (S. C.) Medical Society held its annual meeting in Laurens on December 30th, under the presidency of Dr. William Hastings Dial.

THE DIET QUESTION.

The perennially interesting question of diet, which has been the cornerstone of medical systems and the stumbling-block of the honest and patient practitioner, is beginning to undergo the rigid test of scientific investigation, other than that which is paid for by the manufacturer of absolutely pure and essentially compressed food supplies. The importance of a study of the fundamental principles of nutrition is receiving attention in this country in a series of experiments along the lines of Kuntz and Pettenkofer.

The United States department of agriculture publishes an interesting report of the work done by Professor Atwater and Prof. E. B. Rosa, of Wesleyan University, in "Preliminary Investigations on the Metabolism of Nitrogen and Carbon in the Human Organism."

The manner in which they went to work was simply to put a man in a box and watch him eat, sleep, read, and think, keeping account in the mean time of all the elements of nourishment in the food and air that were administered to him, and subtracting therefrom all the excreta and waste products of his body, and putting down the difference to the energizing quality of the food actually assimilated.

The "box," or, technically, the respiration chamber, in which the subjects were placed for times varying from fifty-four hours to twelve days, was a small, elaborately constructed, triple-walled room, with a window. It was provided with conveniences for eating, sleeping, sitting, and working, as well as arrangements for ventilation and the study of all the metabolic products. Communication with the outside world was afforded by means of a telephone.

The methods of analysis of the food, fæces, urine, air, etc., were essentially those adopted by the association of official agricultural chemists; and the diet of the subject was beef, bread, oatmeal, potatoes, apples, canned beans, pears, peaches, milk, crackers, sugar, cheese, butter, eggs, and water.

In the case of one subject, his occupations were varied—three days were spent in hard mental labor, studying eight hours a day; three days in muscular activity, in using a pulley calling for such energy as would be required in hard labor; while another three-day period was spent reclining, at mental and physical rest.

It was found that, whatever had been the occupation during the day, six hours' rest was sufficient to bring the elimination of carbon dioxide back to a normal quantity, even after the large elimination which accompanied muscular work. In the case of the elimination of nitrogen in the urine, however, the increase upon hard muscular work and the decrease during rest were not manifested until some hours later. With reference to the weight of carbon dioxide given off, it was interesting to note that the amount averaged 900 gm. for the days of rest, and was not increased by mental activity, but that it averaged 1,360 gm. for the days of muscular work; and that during six hours of hard work there was eliminated 513 gm. against 175 gm. during six hours of sleep.

The experiments upon food values showed that when the same person was engaged in severe muscular work the amount of protein burned rose from 78 to 98 gm. a day, and the energy utilized rose from 2,695 to 4,325 calories.

The conclusions are encouraging in the prospects of obtaining a satisfactory balance of income and outgo of energy. They bring out clearly the differences in amounts of nourishment required by different people under different circumstances, and show that muscular work is performed mainly at the expense of the fats, sugars, and starches.

Such work necessarily requires a vast amount of accurate observation before generalizations can be drawn, but the method of work and the description of the apparatus which are given in this preliminary report lead us to hope that the advance work will throw much light upon the working value of foods.

COMPARATIVE FREQUENCY OF STONE IN THE BLADDER IN THE WHITE AND NEGRO RACES.

For very many years the view has been held in this country, and is still adhered to by the majority of medical men, that vesical calculi are much more frequently found in the white man than in the black. Indeed, the old opinion was that the negro race enjoyed an almost complete immunity from this disease. In these days, when time-worn theories are being continually disputed and often upset, it would appear to be but in the nature of things that there should be dissenters from the common belief in regard to the comparative prevalence of stone in the bladder of the two races. Dr. George Ben Johnson is such a dissenter, and states his case with much ability in a paper read before the Southern Surgical and Gynæcological Association, 1895, and now reprinted. It is not denied that stone is less frequent in the negro than in the white, but it is contended that the disparity is not so great as is generally supposed. Statistics are appealed to in order to show that 1 person in every 16,352 is afflicted with a stone in the bladder, the ratio of stone in the whites being 1 in every 11,732, and in the blacks 1 in every 55,305. The presence of stone in the bladder is thus proved to be 4.12 times more frequent in the whites than in the negroes. That the negroes are subject to this disease to a greater extent than was formerly imagined is in all likelihood true, but it is more than probable that they are at the present day more liable to the formation of vesical calculi than in bygone times. Since their emancipation their conditions of life have completely altered, and this is a point which is frequently overlooked. Previously to the abolition of slavery the negroes enjoyed a comparative immunity from many of the diseases from which the white man suffered; for instance, tuberculosis and insanity were almost unknown. After the abolition of slavery they quickly lost this immunity, and now are prone to contract all the diseases of the white man. Dr. Matas, of New Orleans, is of the opinion that the colored man on this continent is at nearly all

points different from his original African ancestors, and it may be said that in their liability to contract diseases the two races in this country are on about the same plane. The more typical African diseases have disappeared or are disappearing, while the liability to contract the diseases formerly peculiar to the white man is increasing in the same ratio. This view of the question will greatly aid in the explanation of the cause of increase of stone in the bladder among the colored people of America. With medical practitioners of the old school the belief that stone was in a large number of instances caused by the quality of the water was almost an article of faith; but this belief has of late been greatly shaken. Dr. Johnson remarks in reference to this that the general opinion of the men whom he had interrogated was that water had no influence whatever upon the production of stone. Roswell Park, Treves, and other writers on the subject say that the formation of urinary calculi is greatly due to the consumption of nitrogenous food. Yet in India, where the complaint is very prevalent, the natives subsist on a vegetable diet and seldom if ever indulge in alcoholic beverages. The causes entering into the formation of stone in the bladder are many, but outside all questions of diet that there are some districts in which the disease is more widespread than in others cannot be doubted.

COAL TAR AS A THERAPEUTIC AGENT.

Coal tar and its preparations as a therapeutic agent are rapidly coming to the front. Among the recent valuable additions to the materia medica are various preparations derived from gas or coal tar, to which a special interest is attached from the not unreasonable expectation that from the same source may be drawn an efficacious remedy for Asiatic cholera. A prominent American weekly, in reference to this matter, says: In the condensing vessels of coal-gas works is a gas liquor from which is obtained the muriate of ammonium. This has a wholesome influence on diseased conditions of the intestinal membranes. It might have been inferred from the many useful medical agents extracted from coal tar that the exhalations from the processes of gas making would be beneficent. As a matter of fact, however, it was not until the exceptionally good health of gas-works employees was accidentally observed that anybody recognized the medicinal value of the gas-works atmosphere. During the last severe epidemic of cholera in Paris, it was noted that those workmen who remained for many hours in the offensive air of the gas works were positively exempt, while those less exposed to that atmosphere were affected by that disease, but to a lower degree than workmen in other occupations. This led Dr. Lemaire to make a systematic study of the subject. Of 25,553 whose health he made a matter of record, 764 were specially occupied with coal tar. These not only experienced an absolute freedom from epidemic diseases to which a large percentage of the others fell victims, but only three suffered from any sickness in the course of seven years. Dr. Bauley, a professor in the Veterinary School at Alport, was the first to call attention to the exemption of the gas workmen from cholera, but nobody undertook to verify his investigations. Now, however, we may look for medical men everywhere to study the subject on the first appearance of Asiatic cholera. In Paris, whenever there is an epidemic of whooping-cough or croup, hundreds of mothers and nurses crowd the yards of the gas works in order to give the afflicted children the benefit of the offensive atmosphere. Although no record is made of the results, the increasing population is an indication that they are favorable.

News of the Week.

Antitoxin Testing.—The New York State board of health has decided to have analyses made from time to time of all the therapeutic serums manufactured in the State, in order to insure the maintenance of a proper standard. The proprietors of the *Pediatrics* laboratory in this city and of a laboratory in Syracuse have been designated by the board as special examiners of antitoxins.

The Other Side of the Hospital Question.—The Presbyterian Hospital of this city, after treating during the past year over twenty-three thousand of the "sick and suffering who appealed for help," finds that its annual expenses exceeded its income by over $72,000! The trustees ask the necessary pecuniary aid from its friends. Rather than close the doors of this model and costly hospital, they would ask for more money. Thus it is shown that there are two sides to the medical charity question. It is too bad that an institution so notoriously discriminative in its charity should suffer pecuniarily. We trust that such of our readers as can feelingly sympathize with the situation, especially the members of the charity-abuse committees, will subscribe accordingly.

Medical Charity Abuse in Boston.—The following resolutions were adopted at the meeting of the Boston Medical Society, on December 18, 1897:

"*Whereas*, The unrestricted abuse of medical charity in the large hospitals and dispensaries of Boston is being seriously complained of by a large number of general practitioners; and

"*Whereas*, The State has granted charters to these hospitals and dispensaries for the definite purpose of giving medical and surgical care and treatment to indigent persons within this city and commonwealth; and

"*Whereas*, The Boston Medical Society, individually and collectively, recognize, with every feeling of sympathy, the right and just claims of some of our citizens to the benefits of public and private charity; and will not be found wanting in generosity in whatever may tend to foster the moral, social, and physical well-being of the sick, the poor, the destitute, the lowly, the worthy, and the unfortunate; and

"*Whereas*, Large numbers of persons of both sexes frequently, daily, and repeatedly receive medical and

surgical advice and treatment gratuitously, for numerous cases of minor surgery and ordinary illness, who are believed to be financially competent to pay moderate fees; and

"*Whereas*, The time, facilities, and attention at the dispenaries being necessarily limited, that which is received by the well-to-do and the undeserving is in that proportion withheld from those who, by the chartered rules of those institutions, are justly entitled to their benefits; and

"*Whereas*, The practitioners of medicine and surgery of any community who have duly graduated from accredited medical colleges, and have incurred the expense of locating in such communities, naturally and justly feel that their present and prospective rights and privileges are wrongly encroached upon by the abuses now in practice in connection with medical charities; therefore,

"*Resolved*, That it is the opinion of this society that some means can be found to check or modify this formidable evil; and

"*Resolved*, That an urgent call be made upon all such members of the profession, who are in sympathy with this movement and have at heart the best interests of the medical profession, to render such moral assistance and financial support in the adoption of such measures as will tend to eradicate and prevent these evils, abuses, and practices; and

"*Resolved*, That an open meeting be held in the near future, and the profession at large be invited to be present; and

"*Resolved*, That a copy of these resolutions be sent to the *Boston Medical and Surgical Journal*, *Journal of the American Medical Association*, MEDICAL RECORD, *New York Medical Journal*, and *Medical News*, for publication.

[Signed for the society.]

"M. GERSTEIN, M.D., *Secretary*."

A Proposed New Harlem Hospital.—Residents in the upper part of the city have petitioned the commissioner of charities and the board of estimate and apportionment to authorize an immediate issue of bonds for the purchase of a site and the erection of a new building for the Harlem Hospital, now located at the foot of East One Hundred and Twentieth Street. The present building is wholly inadequate to meet the calls upon it for the reception and care of emergency cases. Some years ago an appropriation was made of $300,000 for a new building, but for some reason nothing further was done and the money was expended on improvements of other of the public hospitals.

Obituary Notes.—DR. STEPHEN H. CONGER, of Summit, N. J., died suddenly in the railroad station at that place on Christmas eve. He was seventy-six years old, and was a graduate of Princeton College and of the College of Physicians and Surgeons in this city. He leaves a widow and two sons.—DR. S. AMELIA BARNETT, the oldest woman physician, in point of years, in this city, died on Sunday, at the age of eighty-four years. She was a graduate of the Women's Medical College (Homœopathic) in the class of 1865, and had practised continuously for that time up to four years ago, when increasing infirmity compelled her to retire.—DR. H. P. WILSON, of Baltimore, died in that city on December 27th, at the age of seventy years. He was a graduate of the University of Maryland in 1851. He was one of the founders of the Hospital for Women of Maryland, and was ex-president of the American Gynæcological Association, of the Gynæcological and Obstetrical Society of Baltimore, of the Medical and Chirurgical Faculty of Maryland, a member of the Maryland Academy of Sciences, and was connected as gynæcologist with a number of the hospitals of Baltimore.

Antitoxins in Paris.—In France there is a law which forbids the manufacture of therapeutic serums by any one who has not obtained permission from the government to do so. The health authorities of Paris have recently discovered, however, that many of the serums sold by the apothecaries in that city are made by unauthorized parties, and it is believed that, as was recently discovered in the case of a fraudulent tuberculin preparation, many of these serums are absolutely inert.

Yellow Fever in Brooklyn.—The purser of the Clyde Line steamer *New York*, which arrived here from Hayti a few days ago, died about a week after his arrival, with what was pronounced yellow fever. Even if it were yellow fever, there would be no danger of the disease spreading at this season of the year.

The Northwestern Ohio Medical Association held its fifty-third meeting, in Toledo, on December 16th. A number of papers were read by members of the society, and an address was delivered by Dr. Milliken, of Cincinnati.

The Estate of the Late Dr. Evans.—It is announced from Paris that Dr. Thomas W. Evans, the American dentist who died there recently, left all but a quarter of a million dollars of his estate, which is estimated at $8,000,000, to the Thomas W. Evans Museum and Institute of Philadelphia. It is also stated that the heirs, some thirty in number, have decided to contest the will.

Artificial Sea Air.—It is said that in the new public hospital now building in Berlin there is to be a large room in which patients with certain diseases of the respiratory organs and other affections can breathe air which has been impregnated with salt so as to resemble the air of the seashore.

Dr. Harold N. Moyer, of Chicago, the editor of *Medicine*, was held up and shot in the thigh by footpads on December 9th. The deed was committed in the early evening, and near Dr. Moyer's residence on one of the principal streets in Chicago.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending December 24, 1897. December 20th.—Medical Inspector J. G. Ayers ordered to duty at the navy yard, Portsmouth, N. H., January 17th; Medical Inspector

J. B. Parker detached from the navy yard, Portsmouth, N. H., and ordered to duty as member of the naval medical examining board, Washington, January 22d. December 21st.—Passed Assistant Surgeon T. B. Bailey, unexpired leave revoked, and ordered to the Washington navy yard.

Lebanon County (Pa.) Medical Society.—The annual banquet of the Lebanon County Medical Society was held at Lebanon, Pa., on December 7th, and was attended by twenty-seven participants. Dr. J. H. Musser, of Philadelphia, delivered an address on the subject of "Medicine." Other addresses were delivered by Dr. William B. Atkinson, of Philadelphia; Dr. James W. Keiser, Dr. W. M. Guilford, and Dr. S. P. Heilman.

Philadelphia Hospital.—The eleventh annual dinner of the Association of Ex-Resident and Resident Physicians of the Philadelphia Hospital was held on December 8th. Dr. E. L. Duer, vice-president, presided in the absence of the president, Dr. Alfred Stillé. Addresses were made by Drs. H. C. Wood, J. B. Walker, B. F. Stahl, William Pepper, Jr., J. H. Jamar, D. J. McCarty, and others.

Pathological Society of Philadelphia.—At a special meeting of the Pathological Society of Philadelphia, held December 9th, Dr. John Guitéras, professor of pathology in the University of Pennsylvania and surgeon in the Marine Hospital service, delivered an address on "The Epidemic of Yellow Fever of 1897." This epidemic was characterized by the lateness of the season at which it appeared and the mild character of the cases. It was pointed out that many children are attacked, the disease in them passing unrecognized and being diagnosticated malaria, meningitis, pneumonia, etc. This is shown by the increased mortality among white children during periods of prevalence of yellow fever, the colored population being relatively though not absolutely immune. The three most distinctive manifestations of the disease are considered the facies, the presence of albumin in the urine, and a want of correlation between the pulse and the temperature, the pulse being relatively infrequent, while the temperature is high.

Philadelphia County Medical Society.—A stated meeting of the Phil delphia County Medical Society was held on December 8, 1897, the president, Dr. James Tyson, in the chair. Dr. James K. Young read a paper entitled "Accurate Measurement for Scoliosis," exhibiting various forms of apparatus and demonstrating the mode of employment. Dr. Lawrence F. Flick read a paper on "The Treatment of Tuberculosis with Inunctions of Europhen," and exhibited several cases. In addition to the inunctions he employed large doses of creosote. Good results were reported from the method. Dr. H. A. Hare read a paper entitled "The Influence of Digitalis on the Heart Muscle when Administered for a Long Period of Time." He reported a series of experiments that tended to show that animals to which digitalis was administered with their food exhibited greater activity, increased body weight, and increased weight of the heart, with increased size of its muscular fibres, as compared with animals placed under the same conditions but to whose food digitalis was not added. Dr. H. E. Wetherill exhibited a number of medical instruments of precision, and demonstrated the results of some original work. He showed a clinical thermometer capable of recording differences of 0.01° F.; a hygroscope, for determining the degree of moisture of the surface of the body; an inclined-plane vest-pocket microtome; a rotameter; and a small stove for use in the sick-room, that could be folded together and carried in a coat-pocket, and was capable of bringing ice water to the boiling-point within ten minutes. Dr. John B. Roberts exhibited a woman, about fifty-five years old, in whom a considerable deficiency of the nose resulting from injudicious cauterization was made good by autoplasty, first from a finger, and second from the adjacent cheek, with a very acceptable cosmetic result.

A Prize for Physiological Research.—The University of Cambridge has just received, under the will of the late Dr. Joseph Gedge, who died at Khartoum in 1890, the sum of £1,000 for the establishment of biennial prize for original research in physiology.

The Health of New York.—The president of the health board sent to the mayor a few days ago a statement of the death rate of the city for the completed eleven months of 1897. It was 19.62, the lowest on record.

A Memorial of Mr. J. Greig Smith.—It is proposed to commemorate the late Mr. J. Greig Smith, professor of surgery at University College, Bristol, by erecting within the precincts of the University of Aberdeen, of which the deceased was a graduate, a memorial tablet.

Dr. Carlo Saglione, physician to the King of Italy, recently died in consequence of a stroke of apoplexy. He had been paralyzed for a considerable length of time. He is succeeded in his office of medical adviser to the king by Dr. Quirico.

A Sanatorium for Consumptives in New Mexico.—It is reported that the ranch of ex-Senator Dorsey at Chicos Springs, New Mex., will be converted into a large sanatorium for the climatic treatment of sufferers from tuberculosis.

Beriberi is reported as prevailing to an alarming extent in Matanzas, Cuba, new cases appearing among the wretched inhabitants daily.

The First Annual Meeting of the Maryland Conference of Charities and Correction was held in Baltimore in November. Among the subjects discussed was the State care of the insane, feeble minded, and epileptic.

The Maryland Public Health Association held its first semiannual meeting in Baltimore in November. This association is the outcome of a conference of health officers from the State board of health, from county health officers, and a committee on general sanitation from the Medical and Chirurgical Faculty.

At this meeting the principal subjects considered were typhoid fever in connection with water and soil pollution, the dangers from hogpens and slaughter houses in small towns, the sanitary condition of public schools, school life and children's eyesight, and the consideration of the best method of a sewage system for Baltimore.

Ozone.—It may not be generally known that a very simple and effectual way of bringing ozone into the house consists in first suspending moist linen sheets in a keen, dry wind, and afterward hanging them up in the house. The air in the room will thus become considerably charged with ozone and its presence will be easily detected by its peculiar smell, while a moistened starch-iodide paper will instantly turn blue. Why ozone is accumulated in wet cloths in this way is not quite understood, but it may be due to the rapid passage of the oxygen in air over a large wet surface. It is not improbable that this interesting phenomenon plays an important part in the real hygienic cleansing of our linen articles of clothing. In big laundries, when the not quite dry linen is brought in after having been exposed to a cold, dry air for a short time, the smell of ozone is almost more than is agreeable.—*The Lancet.*

Professor Tarnier, of Paris, died recently in that city, at the age of seventy years. He was graduated in medicine in 1857, from the University of Paris, and held the chair of clinical obstetrics in that university at the time of his death. He was well known for his many works on obstetrics.

Proprietary Professorships.—A physician of Chicago recently advertised for a purchaser of his practice, and offered as a special inducement a professorship in one of the medical colleges of the city. We can sympathize with a man who is so anxious to escape from Chicago that he will make the man who helps him a real professor, but we doubt whether the inducement is sufficient. Professors are too numerous these days to count for much.

The Albany Medical College Alumni of Greater New York.—The third annual meeting of this society was held December 3d, at the residence of Dr. William H. Thomson. The following officers were elected: *President*, Dr. Horace Tracy Hanks; *Vice-President*, Dr. John J. Van Rensselaer; *Secretary*, Dr. Warren C. Spalding; *Assistant Secretary*, Dr. Edward F. Quinlan; *Treasurer*, Dr. Henry F. C. Muller.

A Crazy Desire.—A Brooklyn druggist has been arraigned in the police court several times in the past few weeks, charged with practising medicine without a license. The last time he was arrested the jury found him guilty on the charge made, and he was remanded for sentence; but when the case was called it was reported that the man was insane, and the justice had to adjourn the case. The opinion of the officers seemed to be that any man who would risk arrest and imprisonment for such an unprofitable pursuit as the practice of medicine must of necessity be of unsound mind.

The Plague.—The epidemic of the bubonic plague at Poonah and at Bombay is reported to be growing in extent, while the mortality rate is steadily increasing.

Dr. Anthony Brownless, chancellor of Melbourne University, died a short time ago. He was first a practising physician in London, but went to Victoria in 1852, and was the founder of the medical department of Melbourne University. He was vice-chancellor of the university for twenty-nine years, and since 1887 had been chancellor.

Compulsory Vaccination.—In the hope of stamping out the epidemic of small-pox, the officers of the Atlanta board of health have been making a house-to-house visitation in order to vaccinate and revaccinate the inhabitants of the city. A few days ago a fashionable dressmaker of the place refused to submit to the vaccinating physician's salutary operation, and for this she was arrested. A case was made against her and she was fined $25. She pleaded as an excuse that the operation would disable her from earning a living for two children whom a dead sister had left in her care. She said she could not afford to pay the fine, and was sentenced to twenty-five days' imprisonment in the city prison. When she had been there three hours she relented. She was then vaccinated and released.

The Hospital Saturday and Sunday Collections.—At a meeting of the Hospital Saturday and Sunday Association recently held in this city, it was stated that the indications were that the collection for this year would be the largest in the history of the organization. It has been proposed that the two associations in this city and Brooklyn consolidate and issue a united appeal to all the citizens of the greater town.

Congratulations to Sanarelli.—The Italian Society of Internal Medicine, recently in annual session in Naples, sent a letter of felicitation and of admiration to Dr. Sanarelli, "who, in distant lands, while in peril of his life, made such memorable discoveries concerning the etiology of yellow fever, thereby winning for himself imperishable honor and giving to his native land a cause for legitimate pride."

Medical College Courtesies.—When yellow fever appeared in Memphis last autumn, some of the students of the Memphis Hospital Medical College became frightened, just as if they were mere law or divinity students, and the authorities of the college feared they would lose them if once they left the city under no supervision, and so looked about to see what could be done to keep them together. In this emergency a sister institution came to the rescue, and the medical department of Vanderbilt University courteously extended the privileges of the school to the faculty of the Memphis institution, and the latter gladly availed itself of the offer by sending a number of students in charge of the dean to Nashville for a week. Doubtless this kind deed was prompted by no desire to make known to the strangers thus taken in the facilities for medical instruction possessed by the hospitable host.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 16, 1897.

EDWARD G. JANEWAY, M.D., PRESIDENT.

THE meeting was in charge of the section on general surgery.

The Treatment of Chronic Empyema.—DR. B. FARQUHAR CURTIS read a paper on this subject. He said that if all cases of pneumonia were carefully followed for some weeks afterward a certain proportion of the cases of latent empyema would be prevented. Empyema complicated with tuberculosis would not be recovered from in the majority of cases, no matter what the treatment. Diminished resistance on the part of the patient was probably often an important factor in pleural surgery. No granulation production of any amount took place on the interior of the pleural sac, but that some granulation occurred he had been able to demonstrate in his own cases by actual inspection. Very frequently, although drainage had been established, the lung did not expand and the cavity did not fill up.

The Different Operations.—It was certainly due largely to the writings of Estlander that the operation of resection of the ribs had become popular. His idea had been to resect a considerable portion of the ribs over the cavity, and his work was published in 1878. Schede published a very similar method in the following year. His operation differs from Estlander's in removing also the thickened costal pleura, which offers a very considerable obstruction to healing. As the periosteum is left, the ribs are reproduced—sometimes so rapidly as to leave a condition the same as before the operation. The layers of fibrin on the pleura in chronic cases often bind down the lung to such an extent that simple drainage will not suffice to effect a cure. The indication evidently is to resort to evacuation of the pus as early as possible. The majority of physicians and surgeons now believe that incision is the quickest and safest method. The speaker personally believed that free incision is the best treatment for abscesses in general, and hence he could see no reason for not employing it in cases of empyema. Many cases of empyema give a history of small openings having been made, or of small drainage tubes having been used, and removed too soon. If the lung does not expand promptly, it will be more or less crippled by adhesions. General surgical opinion now favors an opening in the chest, low down and far back, together with resection of the rib and the establishment of free drainage. One German authority, it is true, still favors the high incision because of the opening being farther removed from the diaphragm. He would oppose such a view, although he had once known a careful and experienced surgeon, while operating according to the usual rules, to injure the diaphragm and the peritoneum. This led to the patient's death, and subsequent investigation showed that the accident was due to a rare and peculiar distortion of the diaphragm resulting from its adhesion to the chest wall. Having secured thorough evacuation and drainage, the next point for consideration is as to the time for diminishing or removing the drainage tube. After the cavity of the empyema has contracted to a flat space, the tube should always be shortened—indeed, it is well to keep the tube half an inch shorter than the depth of the cavity. Unduly prolonged drainage is apt to result in a chronic sinus or in necrosis of the bone. A not uncommon accident is the slipping of the tube into the chest cavity, without the knowledge of the patient or of the surgeon. The drainage tube should be of good fresh rubber, and should be secured by a safety pin passed through one side. It should be changed whenever it is found that the rubber has become brittle. Schede claimed a fair proportion of cures, even in tuberculous cases of empyema.

Varieties of Chronic Empyema.—In considering the treatment of chronic empyema in detail, the reader of the paper divided the cases into three groups, viz.: (1) total empyema; (2) partial or encapsulated empyema; and (3) pleural fistula. A closed empyema would be found in neglected cases in which the pus had not been evacuated for a long time. Very frequently after drainage had been established, owing to the crippling of the lung, such a case would be found to have been simply converted into an open empyema. The cavity should always be thoroughly drained for a short time before resorting to resection of the ribs. A rather serious complication was the communication of an empyema with a bronchus. Here, the cavity should be drained by a simple incision between the ribs, or at most by the resection of only one rib, the radical operation being delayed until the patient had recuperated somewhat. The radical operation was indicated as soon as it was evident by the contact of the margins of the ribs that the cavity would not further fill up. By means of a long probe it was possible to determine the shape as well as the size of the cavity. Some authorities advocated doing the radical operation after waiting two weeks, but he preferred to wait four to six weeks in the earlier cases, although two weeks might be sufficiently long in the old, neglected ones, from which but little could be expected. In cases presenting a long, narrow cavity, or a "pleural fistula," a cure was most easily effected when the fistula ran parallel to the ribs; in other cases it was usually necessary to resect portions of a number of ribs. In some cases the sinus ran backward so near the spinal column as to require an unwarrantably severe and dangerous operation. Here it was better not to operate.

Technique.—Some surgeons raise a horseshoe flap over the ribs to be removed; others expose the ribs by an "L" or inverted "T" incision. The latter had proved most desirable in his experience. The transverse incision should be parallel to the lowest rib to be removed. The two triangular flaps are dissected backward sufficiently, and then the ribs are resected. If possible, at least one inch more rib should be removed than the diameter of the cavity. It was not necessary to remove as much from the upper as from the lower ribs. After the removal of the rib a thorough exploration of the cavity should be made with the finger, and the incision enlarged. The thickened pleura should be cut away with scissors, and the intercostal artery controlled by clamp or ligature. The cavity having been thus exposed, its walls should be thoroughly curetted and wiped out with pads. The cavity should next be packed with dry sterilized gauze after a large piece of two layers of iodoform gauze had been inserted in the cavity. This gauze should be large enough to fill all the irregular recesses of the cavity. There was less danger of iodoform poisoning by this method than if the cavity was entirely filled with the iodoform gauze. The two flaps of skin should be laid together over the packing. The external dressing did not need to be heavy, and it should be retained until a rise of temperature or the profuse discharge indicated the necessity for renewing it. In the majority of cases there would be more or less sloughing and suppuration, and the discharge would be rather profuse for the first two or three days. In performing the Schede operation he was in the habit of using a vertical incision in the midaxillary line and a transverse one over the lowest rib to be removed. The

amount of blood lost depended largely upon the rapidity of operating, as the hemorrhage should be controlled by pressure from large towels and not from clamps. The anterior and posterior flaps having been retracted and the ribs exposed, each rib in turn should be cut out subperiosteally. Schede divides each rib in the centre with bone forceps and breaks it off, but the speaker preferred to divide the rib with cutting forceps at each side of the wound. The enormously thickened tissues could usually be divided with very stout scissors. In this way the wall of the abscess cavity was freely exposed by a large triangular opening. The ragged edges of the divided ribs should be covered by tacking the skin over them. The cavity should then be curetted and packed. It would be noted that there was not much practical difference between the operations of Estlander and Schede, except in the treatment of the skin. The Schede operation was especially suitable for cases of total empyema. When the pleural destruction had not been very extensive, granulation should be well under way at the end of a week. After the granulations had once started, iodoform could be used more freely, as there was less danger of absorption. Schede asserted that even in seemingly desperate cases it would be found that the lung would often expand considerably, and this had been his own experience. The first deformity produced by these radical operations was truly startling, yet in the course of a year or two it would be impossible to see that such an extensive operation had been done. Some condemned the operation in children because of the deformity, but in his experience the lateral curvature remaining was no greater than in every case of empyema in which the ribs lay in contact.

Forcible Expirations Aid Recovery.—Convalescence should be assisted by forcible expirations, *e.g.*, with a spirometer. The time necessary for recovery depended mainly upon the size of the cavity. Schede states that at least a year generally elapsed before complete recovery in total empyema. Of the speaker's three cases of total empyema, recovery was exceptionally rapid in one, the patient being discharged in three months and a half. In another patient the cavity filled up, but would not cicatrize owing to poor general condition. In the third case, that of a boy of seven years, the lung expanded to the surface of the chest in the course of three months, but, owing to some ill-defined constitutional taint, he relapsed. Death occurred one year after the operation.

In conclusion Dr. Curtis said that one should not be alarmed at the apparent severity of the operation, for even the weakest patients bore it well if it were done rapidly and skilfully. The secret of success lay in using slight anæsthesia and in the easy control of hemorrhage. Considering the incurable and dangerous condition for which the operation was undertaken, the risk was not too great a price to pay.

Dr. R. F. Weir said that his experience with Schede's operation was limited to four cases, two of them being examples of total empyema. In none of them did he resect higher than the fourth rib. He had found that the ribs did not snap off as Schede claimed they did when they were divided only in the centre. De Bove, of Paris, had suggested that the thickened layer should be peeled off the lung to such an extent as to allow the lung to expand rapidly and fill the cavity of the chest. Dr. Weir said that he had been waiting for an opportunity to test this method, for, if it proved successful, it would be a very valuable procedure, enabling one to avoid the dangers of Schede's operation, the chief of which was hemorrhage. Moreover, De Bove claimed that only one, two, or three ribs need be removed, thus greatly simplifying the operation.

The Operation a Grave One.—Dr. A. G. Gerster said that cases of extensive chronic empyema were now very much less common than they had been ten or fifteen years ago, undoubtedly because the cases were at the present time more promptly operated upon. One should be careful not to underestimate the dangers of the extensive operation described in the paper, for they were great. The most skilful operator would find himself confronted with serious depression arising from the profuse hemorrhage. It should be borne in mind that even cases in which the cavity of the empyema communicated with a bronchus were amenable to a cure. He had had one such case during the past summer. The danger of flooding the sound lung during the progress of the operation was certainly a very grave one, but this could be avoided by performing the operation without any anæsthetic, unless it were a local anæsthetic. He could confirm what had been said in the paper about the very remarkable disappearance of the extensive deformity. Even though a case of chronic empyema might seem desperate, the surgeon was not justified in looking upon it as incurable, as was formerly done. He had had bad cases in which he had done the old Estlander operation, but the ribs had filled in so quickly that it had become necessary to repeat the resection one or more times. Even under such circumstances he had obtained a good result.

Dr. F. W. Murray said that his experience comprised only four cases, yet these had served to exemplify the danger of tuberculous infection when there had been improper drainage and treatment. The result might be as good in children from simple incision, but he was in favor of resection of rib in all cases. Notwithstanding the apparently formidable nature of the operation described in the paper, the results were remarkably good. Of one hundred and thirty-five cases collected by a German writer, in which extensive rib resection had been done, fifty-six per cent. healed without fistula, and death directly followed the operation in only four cases.

Self-Inflation of the Lung.—Dr. Andrew H. Smith said that while the comparative rarity of cases demanding such radical procedures was largely the result of better knowledge and treatment, it was also in part owing to the plan of inflating the compressed lung by means of the spirometer or a similar device. Some years ago he had demonstrated that the lung could be reinflated by closing the nostrils and making an expiratory effort, the air being forced over from the sound lung into the collapsed one. In cases in which the thickening had not become very extensive, it was perfectly possible to facilitate the inflation of the affected lung in the simple manner alluded to. The patient should be instructed to make this expiratory effort twenty times or more a day, and it could be carried up to the point of tolerance of the individual.

Dr. Curtis, in closing, said that in his experience the loss of blood had not been so great as he had expected it to be, and not enough by any means to exsanguinate the patient.

Regulation of Midwives.—Dr. N. E. Brill said that under the present laws the midwife had no legal status in this city. The Society of Medical Jurisprudence had recently drawn up a bill, for presentation to the next legislature, having for its object the proper regulation of midwives. Briefly, this bill provides that all midwives must be licensed by the regents of the university, and the license must be registered in the county in which they practise. Such license is to be issued only to persons of good moral character, who can read and write, and who have satisfactorily passed through a prescribed course of study of at least a year's duration. The State board of health is empowered to make regulations for midwives from time to time. The licenses may be revoked by the board for cause.

Dr. Brill then moved that a committee of three be appointed by the chair to confer with the committees of the Society of Medical Jurisprudence and of the county societies of New York and Kings. According to the rules regarding new business, no action can be taken until the next meeting of the academy.

Election of Officers.—The following officers of the academy were elected: *Vice-President*, Dr. W. H. Katzenbach; *Recording Secretary*, Dr. Louis Faugères Bishop; *Corresponding Secretary*, Dr. M. Allen Starr; *Treasurer*, Dr. Henry E. Crampton; *Trustee*, Dr. A. M. Jacobus; *Chairman of Committee on Admissions*, Dr. Henry Ling Taylor; *Committee on Library*, Dr. Edward D. Fisher.

SECTION ON GENERAL MEDICINE.

Stated Meeting, December 21, 1897.

LOUIS FAUGÈRES BISHOP, M.D., CHAIRMAN.

The Diet of Dyspeptics.—DR. MAX EINHORN read a paper with this title (see page 7).

Digestion the Cure for Indigestion.—DR. WILLIAM H. THOMSON said that the vastness of the subject selected for discussion this evening reminded him of the title of a certain book, "Five Days in Africa." The class of patients to which the reader of the paper had especially referred included a very large number of women. The physician too often accepted without question the statements of patients regarding their inability to take certain articles of food. He had long been of the opinion that the greatest cure for indigestion was digestion; in other words, we must find out just what was the patient's digestive capacity. He had often found that the patient could digest a certain nutritious article of food, and on this the nutrition had been improved very decidedly before the dietary was enlarged. If one were fortunate enough in the individual case to discover such an article of food, the treatment would be greatly simplified. It was well to inquire of the patient what articles of food were first noticed to "come up" in the mouth, or "repeat" after eating, and such articles it would be well to avoid. Many individuals would declare that they could not eat bread, yet there were "breads" and "breads." In his experience the crusty Vienna bread was exceedingly useful in cases coming to him from the country after having been accustomed to the heavy, sour bread sometimes found in rural districts. The quantity taken was also of much importance. In these cases of malnutrition emaciation was frequently present, but it should be remembered that emaciation is a great deal more than thinness—it is a loss of bulk of every tissue in the body except the nervous tissue. By passing in review the various causes of emaciation, it was comparatively easy by exclusion to diagnosticate those very common cases of malnutrition due to functional dyspepsia. These patients were very often starving themselves from fancy.

The Palate Rules Supreme.—The nervous system had much to do with the loss of relish for food, and in laying down rules for dyspeptics one must give much weight and consideration to this matter of relish. Many people are hungry, and yet have no relish for food. This is distinctive and peculiar to the human subject. The palate constitutes itself a court from which there is no appeal, and, no matter what the teachings of physiological chemistry, this court renders the final decision. Many of the cases under consideration, it would be found, had originated in a nervous derangement whereby the relish for food had been lost.

New York Chicken Poisonous.—DR. GEORGE B. FOWLER said that the books classified dyspepsias and multiplied them, and experts gave a distinct symptomatology for each variety, so that the average physician was confused and discouraged. But if he had sufficient common sense he would usually come at last to take a matter-of-fact view of the subject, and would put his dyspeptic patients on a rational but fairly liberal diet. Personally he believed, with Sir William Roberts, that it was not so much in many instances what one ate, as the amount taken. He was a strong believer in the value of bread and butter. In these patients the mind became concentrated upon the stomach, and hence the moral treatment—getting control of the patient—was a very important element of success. Concerning special articles of food, he wished to say that it was wise to avoid turkey, chicken, hashes, and stews. He regarded chicken and turkey, as found in the markets of New York City, as nothing short of an absolute poison. Personally he would no more think of eating roast chicken than he would of taking four grains of arsenic, and he had had numerous patients who had suffered dreadfully for a long time from colics, and had even been thought to be suffering from gall stones, when in reality their distress was owing to indulgence in chicken. This had been proved by the quick and permanent relief experienced in simply avoiding this article of food. Hashes and stews should be placed in much the same category.

Attend to the Teeth.—DR. W. H. KATZENBACH said that in considering the matter of diet it was important to remember that the food should be adjusted to the age of the patient and the condition of the teeth. This, of course, implied that the natural teeth should be put in as good condition as possible, or artificial teeth substituted for them.

Three Guiding Principles.—DR. C. E. LOCKWOOD remarked that a recent writer, in speaking of dietetics, had very well said that the quantity of the food should be determined by the motor activity and the sensibility of the stomach, and the quality by the digestive power of the gastric juice. Many women, when troubled with nervous dyspepsia, were inclined to restrict the diet to such an extent as to impair their nutrition. There were three important points to remember in the treatment of such cases, viz.: (1) to get the confidence of the patient; (2) to limit the quantity of the food; and (3) to give small doses of sedatives to allay the irritability of the stomach. As an example of the power of the mind over the stomach, the speaker cited a case of colloid carcinoma of the stomach, in which only an exploratory operation had been done. Before the operation the patient had been losing flesh rapidly, but since the operation, not knowing that the disease had not been extirpated, he had regained thirty-five of the fifty pounds that had been lost, and had ceased to vomit and complain of distress. Notwithstanding this apparent improvement, the physical signs indicated a decided extension of the disease. In a general way he would advise treating these cases by giving at least six meals a day, a small quantity of a varied diet at a time, together with ten grains of bromide, three or four grains of chloral, and two or three minims of tincture of belladonna in chloroform water before eating. In this way he thought he had diminished the sensitiveness of the stomach so that the patient had been able to bear the food much better. He also favored a pretty dry diet.

Eat Slowly and be Merry.—DR. F. A. BURRALL spoke of the amount of mischief done by the very common habit of eating the meals rapidly, according to the farmer's motto of "Quick to eat and quick to work." Thorough mastication was of the utmost importance, and, of course, this presupposed a proper condition of the teeth. Gastric digestion was often weakened and much distress was caused by the ingestion of too much fluid with the food, particularly at the beginning

of a meal. Another factor in causing dyspepsia was the habit of eating food in silence, or without that mirth and good fellowship so necessary to insure a nervous condition favorable to the normal action of the digestive organs. These little details might seem trite and unimportant, but it was the duty of the careful physician to instruct his patients in regard to them. The long-continued and free use of digestive agents served to make the digestive organs lazy and inactive. At the present time there seemed to be a tendency to return to the more common use of mercurials. He had himself known of one case in which three grains of mercury with chalk had been taken almost nightly for a year without anything but good resulting. If the cause of the dyspepsia did not seem clear after careful examination, it should be the rule to examine the urine, as in disease of the kidney one would often find the key to the situation.

Eat Crusty Bread.—Dr. W. H. Weston said that he wished to speak a word in favor of bread. Dr. Thomson had spoken of crusty bread as being easily digested, and to this he would heartily assent, but he would go further and recommend that the bread should be almost all crust. If hash were properly made it should be quite digestible.

Dr. Einhorn, in closing the discussion, said that his paper dealt only with cases of chronic functional dyspepsia, but his cases were not confined to those exhibiting anorexia. In some of those referred to, the patients had had a good appetite, but had had distress after the ingestion of food. It was this that gave rise to the "fear of food." Even in the cases of hyperchlorhydria he did not favor a one-sided diet for more than a short time. He could not agree with Dr. Thomson that we should be governed in our selection of food by the question of whether or not the taste of the food was "repeated," for not only did such a rule seem to him unreliable, but it was not wise to encourage the patient in this way to practise introspection. He had never seen any harmful or poisonous effects from the ingestion of chicken or turkey when properly prepared; certainly the white meat could be digested by most persons. Regarding the case cited by Dr. Lockwood as evidence of the mental impression produced by an exploratory operation, Dr. Einhorn said that he had had an exactly similar case, but he was not inclined to accept the explanation given. The improvement could hardly be attributed to a purely neurotic influence, because certainly a person with carcinoma of the stomach had abundant reason to vomit and complain. It was rather an instance, of which tuberculous peritonitis was another familiar example, of a mysterious and inexplicable influence exerted by an exploratory laparotomy. In his own practice he sometimes prescribed the bromides to reduce the sensitiveness of the stomach in dyspeptics, but it did not seem to him a very essential part of the treatment. He did not give his patients a dry diet, but limited the quantity of fluid at a meal—say to about ten ounces. If we restricted the fluid too much, the food could not be taken with a relish, perhaps not at all. The first principle of our treatment should be to make the patient eat.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, December 23, 1897.

Simon Marx, M.D., Chairman.

Enucleation of Large Interstitial Fibroid without Hysterectomy.—Dr. Frederick Holme Wiggin presented a married woman, forty-two years of age, who had been admitted to the gynæcological ward of the City Hospital on July 12, 1897. The first menstruation had occurred in her fourteenth year, and thereafter had been of the monthly type. She had not been pregnant, and her last period had occurred shortly before admission. Four years ago her attention had been called to the fact that her abdomen was enlarging. After the first year the tumor seemed to diminish in size for a short time, and then began to grow rapidly. It had caused no distress until recently. Examination showed a large tumor which seemed to be connected with the uterus. She was weak, suffered from nausea, and could not eat solid food. On July 19th, after the usual preparation, the abdomen was opened by an incision through the left rectus muscle. The tumor was found to be an interstitial fibroma, and was rapidly shelled out of its bed. This was considered better than an abdominal hysterectomy, owing to the feeble condition of the patient. Three buried sutures were inserted, and the walls of the cavity in this way approximated. The peritoneum was brought over the line of incision by a Lembert suture. Very little blood was lost during the operation. The right ovary being cystic, it was removed. The abdominal cavity was irrigated freely with saline solution before the wound was closed, and about one quart was left in the cavity. The pulse had been very weak at the beginning, and after the operation the patient did not rally well. At the end of three hours the pulse became imperceptible, and she was given a large intravenous saline infusion. It was necessary to repeat this about two hours later. After this her convalescence was very good. Dr. F. M. Jeffries, who examined the tumor at the Carnegie Laboratory, reported that it was a fibroma rather than a myoma. The tumor after removal weighed a little over ten pounds. The patient has not menstruated since the operation.

Virginal Endometritis.—Dr. Louis J. Ladinski presented a girl of fourteen years, who began to menstruate in her eleventh year. She flowed rather profusely at each period up to about a year ago, and from that time until she came under observation she had almost constant hemorrhages. When first seen, November 1st, she was pale and poorly developed. The depth of the uterine cavity was about three and one-half inches, the os was patulous, and a grumous material was oozing from the uterus. A curettage was done for diagnosis. It was thought at the time that the uterus was possibly the seat of tuberculosis or malignant disease. Microscopical examination, however, proved the case to be one of ordinary fungoid endometritis. The uterus had since then diminished in size and the hemorrhages had ceased. The sputum had also been examined on several occasions, but no tubercle bacilli had been found. No cause could be assigned for the endometritis except her poor general condition.

Instrument for Establishing Vaginal Drainage.—Dr. Philander A. Harris exhibited an instrument which he had found very convenient in establishing drainage through Douglas' cul-de-sac. The point of the instrument is like that of the Cleveland ligature carrier, and it is stoutly made. With it the vaginal roof can be punctured, the opening enlarged, and then the gauze drawn back through the opening.

New Portable Operating-Table.—Dr. Harris also exhibited an operating-table intended for use in private houses. It is made largely of wood, with braces of steel and aluminium, and, while very light, was demonstrated to be capable of holding on one end a person weighing one hundred and eighty pounds. One peculiar feature of the table is the fact that when it is fixed for the Trendelenburg posture the field of operation is not elevated above the level which the table assumes when used in the ordinary position. The table weighs twenty-seven pounds.

Dr. H. N. Vineberg said that he had examined the case presented by Dr. Wiggin. He found the uterus

slightly enlarged, but in fairly good position. Of course, if the patient had been in better condition at the time of the operation, it would have been better to remove the uterus entirely, in view of her age. Almost from the beginning he had made it a practice to make the incision through the rectus muscle, and he was therefore interested in noting that it had been so made in this case. Certainly the scar and the result were excellent, and he felt in his own cases that whenever he could make the incision outside of the linea alba the chances of getting good union were better.

Dr. E. B. Cragin said that he believed in the future surgeons would operate more and more according to this plan—*i.e.*, myomectomy. It was still somewhat uncertain as to how useful these uteri would be after having had three or four fibromata removed from them. The fact that it could be done without danger had been demonstrated by the case just presented, but it did not follow that it was necessarily the best method in all cases.

Dr. Harris thought there was a limited field for work of this kind, provided there was a certain indication—*i.e.*, not too advanced years. In a patient of thirty-three or thirty-five years, with a prospect of child-bearing before her, the operation of myomectomy should be the one of election. The field for the operation was necessarily limited, because fibroids were usually met with toward the close of the child-bearing period. He had removed a tumor of the size presented, in six minutes, by what Dr. Kelly calls "continuous incision." Although Dr. Kelly had operated in this way many times, none of his patients had become pregnant since the operation. This, of course, was to be expected, yet it seemed to him that the operation represented an extreme conservatism.

Dr. H. L. Collyer said that the case was a valuable one, if only because it served to encourage others to practise greater conservatism. When the pedicle was thick the tumor could usually be enucleated as easily as hysterectomy could be done. The large tumors were apt to be complicated with many adhesions. In some of these cases he had adopted the plan of gathering up the sac, stitching it to the abdominal wall, packing the sac, and allowing it to granulate. This was far better than attempting to tie off numerous adhesions.

Dr. A. E. Gallant said that Martin, of Berlin, had had pregnancy follow more than once in cases so treated.

Dr. Wiggin said that there had been no adhesions and no difficulty in enucleation. There was some ascitic fluid present, and it had been his experience that when such fluid was present the adhesions were usually very slight. It was for this reason that he had left some saline fluid in the cavity after the operation. The whole operation occupied only about thirty minutes. In several instances he had enucleated small fibroids from the posterior wall of the uterus through a vaginal incision. It was important not only to close the cavity by buried sutures, but also to bring over the peritoneum by means of Lembert sutures, in order to guard against infection. As an additional precaution, it was his custom to disinfect the tissues with pyrozone. He saw no reason why many of these women should not afterward conceive and bear children, and hence he did not look upon the field of the operation as so limited as Dr. Harris seemed to believe.

Dr. Collyer, referring to the case of virginal endometritis, said that the anterior vaginal wall was very short, as were also both broad ligaments, as though the girl had had a peritonitis. He had known children of even five years to participate in sexual excitement with the opposite sex, and he was inclined to believe that in the present instance the endometritis had some such origin.

Dr. Vineberg objected to the use of the term "virginal" as absurd and misleading. Many young girls, he said, developed an endometritis shortly after the establishment of the menses. The shortness of the anterior vaginal wall and of the broad ligaments would seem to indicate an imperfect state of development, and this would also point to endometritis entirely independent of any sexual excess.

Dr. J. Milton Mabbott said that from the history and appearances presented by this young girl he was inclined to doubt the fact of her being a virgin.

Dr. Ladinski said that not only from the clear history obtained, but from the condition found at the time she came under observation, he still felt positive that this was an example of endometritis occurring in a virgin.

Dr. John Polak said, regarding the operating-table presented, that in those tables in which the fixation of the legs of the patient was depended upon for holding the weight of the body, he had found that the popliteal circulation was apt to be interfered with and that the recti muscles were made unduly tense. He preferred a table on which the patient was supported, while in the Trendelenburg posture, by the shoulders.

Dr. Vineberg, speaking of the vaginal instrument presented, stated that it was well to caution the surgeon against allowing an assistant to pass an instrument of this kind in cases in which there were extensive adhesions.

Dr. Harris replied that in using the instrument he of course passed his own finger down from above and outlined the uterus, while the assistant passed the instrument against his finger; hence it was difficult for him to understand how harm could be done with the instrument. Regarding the table, Dr. Harris said that he had had three very disagreeable cases of paralysis from the use of shoulder supports in connection with the Trendelenburg position.

A Fœtal Monstrosity. — Dr. Henry M. Hazen presented photographs of a fœtal monstrosity. It was a male child, born at full term. A large encephalocele corresponded to the position of the anterior fontanelle, and there was a smaller one posteriorly. The parietal bones were absent; the lower part of the frontal bone only was developed; the left testicle and the right thumb were absent. The child also presented a harelip and a cleft palate.

Subperitoneal Lipoma Mistaken for an Incarcerated Hernia.—Dr. Leonard S. Rau presented a lipoma removed from a stout woman of forty years, who had, twelve years ago, after a confinement, first noticed a small mass in the groin. When this mass protruded much she had been accustomed to reduce it by digital pressure, but on September 20, 1897, for the first time it could not be reduced. On September 23d, when first seen by him, it was still unreduced. It was hard and about the size of a hen's egg. It could not be reduced by gentle taxis, so immediate operation was advised. Her general condition was excellent. The case was believed to be one of incarcerated inguinal hernia, and from the denseness of the mass it was assumed that the sac was very thick. He operated the same afternoon, and found the tumor surrounded by a thick capsule. The tumor was attached by a very long pedicle of peritoneum, which passed into the abdominal cavity. He carefully followed it up to the uterus, and positively excluded an ovarian hernia. The pedicle was ligated, the tumor removed, and the wound treated as in an ordinary Bassini operation. The wound healed by primary union, and the patient was allowed up on the tenth day. The mass measured six by five centimetres, and presented the appearance of fatty tissue between masses of fibrous tissue. The tumor was reported by Dr. Elsner to be a pure lipoma.

Dr. Rau said that he had been unable to find more

than a few reported cases of subperitoneal lipoma. As a rule, the prognosis was good, and treatment consisted in removal of the tumor. The chief points of interest in the case related were: (1) the ability of the patient to reduce the tumor for so long a time; (2) the fact that it finally became irreducible; (3) the fact that, owing to the existence of the long pedicle, it must have floated free in the peritoneal cavity when pushed back; and (4) the differential diagnosis. The irreducibility was probably owing to an increase in the size of the tumor.

Post-Partum Eclampsia with Uterine Hemorrhage.—Dr. R. Abrahams said that in 1895 he had been called in to see a woman in confinement with her ninth child. She had long suffered from chronic Bright's disease, and her urine always contained some albumin and casts, but at no time was there any general œdema. He had attended her in two previous confinements. When he arrived this time he found a midwife, a dead child, and a partially delivered placenta. After completing the delivery, and just as he was about to leave the house, he noticed evidence of an impending attack of eclampsia. She had within a few minutes three eclamptic seizures, and then such a severe uterine hemorrhage that it became necessary to pack the uterus. Before this could be accomplished, however, she was pulseless. She was restored by injections of saline solution and of ergot and strychnine. The patient made a good recovery, and was out of bed on the tenth day.

Fœtal Dislocations.—Dr. Abrahams also reported three cases of dislocations occurring in the fœtus at the time of delivery. In the first case the child had been delivered by a midwife after violent traction, the child presenting by the breech. There was a dislocation of the hip. In the second case there was a double dislocation of the lower jaw, brought about by efforts at delivering the after-coming head. He had reduced the dislocation without difficulty. The third case was an upward dislocation of the sternal end of the clavicle, produced by a pernicious practice prevailing among the ignorant classes of manipulating or "measuring" the limbs of a newborn child.

The Statistics of Lying-in Institutions.—Dr. H. N. Vineberg said that certain lying-in institutions, particularly those having an out-patient service, often published remarkable figures, showing the immunity from sepsis in large numbers of cases, in spite of repeated examinations by physicians and students. But such statistics did not by any means tell the whole truth, as the following case would serve to emphasize: A woman, twenty-three years of age, had been delivered by forceps a few years ago in such an obstetric service. She had a normal and ideal puerperium, and was up in a few days, but she soon found that every few weeks it became necessary for her to give up her work and go to bed. She grew steadily worse, and was finally sent to him by Dr. Rau. Examination showed a semi-elastic mass like an abscess, between the vagina and rectum. The uterus was in good position; the cervix was much torn; a large mass could be felt to the left side of the pelvis, extending down to the other mass. The patient was etherized and an opening made into the first mass posteriorly. This gave exit to some serous fluid and pus. On introducing his finger he found another cystic mass, which when punctured was found to contain pus. Other masses being detected by examination, he made lateral incisions, pushed back the bladder, and cut away the cervix (according to the method of Ségond), so that the uterus could be delivered through the anterior incision. It being impossible to deliver the mass on the other side, the adnexa were clamped, the uterus was delivered, and a much swollen and elongated tube removed. A pyosalpinx and a multilocular ovarian abscess were found on the left side. The specimens were exhibited. Dr. Vineberg said that there was no doubt in his mind that the woman had originally had an infection in the left tube and ovary. It was in just such a case as this that the French operation from below was specially indicated. During the whole operation the intestine was entirely out of the way. It seemed to him that in a case of this kind the surgeon could work more safely and intelligently from below than from above.

Dr. Ladinski said that in the last two weeks he had had three cases illustrating the absolute necessity of operating under such circumstances as were present in Dr. Rau's case. The first of his cases was one in which the tumor had become irreducible only within the past four or five months. It proved to be an incarcerated omental hernia. In another case the tumor had existed for a number of years. A physician reduced part of the tumor, and then applied a truss. When he saw the case there was an abscess. He found that there had been a hernia which had ruptured, leaving a fæcal fistula. In still another case, occurring in a woman of about sixty years of age, the appearance was that of an ordinary omental hernia. Taxis had already been tried without success. The pulse was rapid and the patient was beginning to vomit. On operation, the hernia was found to be intestinal and the bowel in an advanced state of gangrene.

Dr. Vineberg said he thought the proper line of treatment had been followed by Dr. Rau. Even though it might have been possible to reduce the tumor, it was safer not to make prolonged taxis. He knew of one such case in which death had followed persistent efforts at reduction.

Dr. F. Pirkner said that about one week ago he had seen a girl infant of two months, with a tumor like that in Dr. Rau's case. It had been first noticed about a month ago, and by exclusion he had made the diagnosis of lipoma. He should watch the case with increased interest.

Dr. E. W. Peet said he believed the case of eclampsia reported by Dr. Abrahams was saved by the uterine hemorrhage and the consequent rapid elimination of the poison. He cited a case of severe eclampsia, occurring in the practice of a country practitioner, in which the successful result seemed to be entirely attributable to a very free venesection.

Dr. S. Marx said that the remarks of Dr. Vineberg called to his mind some remarkable statistics published by one institution. He was in a position to assert that the apparent exemption from sepsis and mortality in the lying-in wards was because it was the custom there to transfer a case to the gynæcological service as soon as there was evidence of sepsis or a fatal termination was expected. If the morbidity were given, the statistics of these outdoor departments would be very different.

Dr. Gallant said that in a certain rural district he had learned from conversations with the people living there that it was not uncommon for as many as three in one family to die of puerperal fever. It was necessary to send ten or fifteen miles for a physician, and it was customary for the physician to make only two visits after delivery. Such a frightful mortality from a disease brought on by the physician's own lack of cleanliness could not be too severely condemned.

Dr. Abrahams said that the statistics of lying-in institutions were very misleading for another reason—*i.e.*, if sepsis or other serious complication developed the physicians from these institutions would be discharged by the family, and some private physician would be summoned to take charge. He had seen many cases of this kind.

Dr. Vineberg, in closing, said that at the present time among the better classes an extreme view was

held regarding the occurrence of sepsis, so that if in spite of great care the temperature rose the physician was at once blamed. So strong was this feeling now that some physicians, in self-defence, abstained from having the temperature taken in obstetric cases.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 20, 1897.

J. Blake White, M.D., Vice-President, in the Chair.

Necrosis of the Hip.—Dr. Thomas H. Manley presented a little boy who, three years ago last May, fell down into a cellar and sustained some injury of the left hip. After hospital treatment for some time without benefit, the child was brought to him. At this time there were much emaciation and a temperature of 104 F. Being convinced that there was necrosis present, he made an incision down to the diseased area, and found this to be the case. Within four months the bone was entirely regenerated, and the child had now regained his health as well as good use of the limb. The shortening at the present time was exactly the same as at the time of the operation—one and one-half inches.

Resection of the Inferior Maxillary Nerve for Neuralgia.—Dr. Manley then presented a man who, five years ago, began to have a peculiar trigeminal neuralgia affecting the region of the lower jaw on one side. So great had been the pain that he had been unable to obtain proper nourishment and sleep. Accordingly, under cocaine anæsthesia, Dr. Manley had trephined and exsected a portion of the inferior maxillary nerve. The relief was immediate, and continued for three years. For the last three months the man had again suffered from pain in the same region, but not of a very severe character. It was the speaker's intention to perform another resection of the nerve should the pain become sufficiently severe to demand it.

Dr. Edward von Dönhoff said that the result in the little boy was very satisfactory indeed. It was never safe to operate in such a case unless one could quite positively define the existence and extent of pelvic disease.

Dr. Achilles Rose said that it had been demonstrated by experiment on animals that every joint could be resected and its function still be preserved, provided the periosteum was saved. He had himself made a resection of the ankle-joint, with a perfect functional result.

Dr. A. E. Gallant referred to a case of tic douloureux in which Dr. Hartley had resected nearly three centimetres of the nerve. At that time Dr. Hartley had made the statement that if less than 2.5 or 3 cm. was resected there would certainly be a recurrence of the neuralgia.

Some Remarks on Mechanico-Therapeutics.—Dr. T. J. McGillicuddy read a paper with this title. He said that it was an undisputed fact that lack of exercise was a cause of much ill-health. Systematic and uniform physical exercise, under medical direction, was to-day a prominent method of curing many ills. It was especially applicable to the deformed, the convalescent, the feeble, the aged, and those engaged in sedentary occupations. Among the more immediate results of such exercise were increase in the strength of the heart beats, greater activity of the excretory and secretory organs, and an increase in the size and strength of the muscles. The exercise should be adapted from the beginning to the strength of the patient, and increased according to the same rule. Cardiac hypertrophy and albuminous urine were often the result of overexertion. It was necessary to ascertain for each patient the amount of exercise requisite to produce "normal fatigue." In November, 1895, in a paper read before this association, he had insisted upon such work being entirely under medical supervision. It would be better if the word "massage" was abandoned by the profession, because it had become debased. A better expression would be "manual treatment." It was only in this country that the lay massage operators were allowed to occupy the position they did. If physicians would devote their attention to manual treatment, as applied to special organs, and leave the general rubbing to nurses, much would be done in the way of keeping this valuable method of treatment from the hands of quacks. Cold and heat were valuable cardiac and vascular stimulants, and their application through hydrotherapy was a useful part of mechanico-therapeutics. The circulation of the blood and lymph was greatly influenced by the action of the muscles. Where the latter were inactive, scientific physical exercise would quickly restore the normal balance of the circulation. He knew of no other method of treatment that would so quickly increase the breathing-capacity; he had known it to be trebled in a few weeks. Thus a young anæmic girl, who had been taking Blaud's pills for a long time without benefit, had a breathing-capacity of fifty cubic inches on beginning treatment. In four weeks it had increased to one hundred and thirty cubic inches. In brief, it might be said that mechanico-therapeutics was useful: (1) in many chronic digestive disorders; (2) to increase assimilation; (3) to increase vital action in cases of debility; (4) to regulate muscular action, as in various distortions of the spine resulting from unequal muscular action; and (5) to increase the lung capacity.

Dr. H. J. Garrigues said that the term "mechanico-therapeutics" covered a very large field, and might even be made to include surgery. Hydrotherapy came within this field, not only by reason of it being a convenient mode of applying heat and cold, but because it was capable of accomplishing much in a purely mechanical way. The practice of massage was probably a thousand years old, but it was not generally brought to the attention of the medical profession until about a quarter of a century ago. He had had the good fortune to learn this method shortly afterward, and it had soon become popular in the Scandinavian countries, owing to the fact that it had greatly benefited a member of the royal family of Sweden.

Massage Excellent for Acute Synovitis of the Knee.—Dr. Garrigues said that for such a troublesome condition as acute synovitis of the knee he knew of nothing that could be compared to proper massage of the limb twice daily. Under this treatment the patient was allowed to continue at business, and recovery was more rapid and satisfactory. As a rheumatic individual he could speak from personal experience of the great relief afforded by massage. He had seen a case of sciatica cured within two weeks by this treatment. Of late years massage had gained recognition in a new field of surgery—in the treatment of fractures.

Pelvic Massage.—Regarding the application of massage to gynæcology, the speaker said that it too had been introduced by a layman—Brandt. There was not the slightest doubt that the uterus could be made to stay in the body by mere massage and gymnastics, but the great drawback to it was that the treatment was very tedious, each séance requiring one-half to one hour. In his own experience the treatment had been restricted to pelvic inflammations. If there was the slightest suspicion of the presence of an abscess of any kind in the pelvis, the treatment was positively contraindicated—indeed, its use in such cases would be quite likely to cost the patient her life.

Nature Cures.—Dr. S. Baruch said that forty years ago Oliver Wendell Holmes had said that if all the medicines were thrown into the sea it would be better for humanity and worse for the fishes; but the great truth embodied in this sarcastic remark had been slow to dawn upon the medical profession. We were losing sight of the old Hippocratic idea that "nature cures"; that those agencies which maintain health—fresh air, exercise, rest, diet, cleanliness inside and outside of the body—are just as valuable in restoring health when it has been lost. It was, therefore, very gratifying to listen to the paper just presented.

Hydrotherapy.—Hydrotherapy consists in the application of heating and cooling effects in a systematic manner; there is little or no mechanical effect from such treatment. The circulation of the blood consists not only in the propulsion by the heart, but in the action of the elastic fibres in the capillaries. In cases of grave toxæmia, such as typhoid fever, these fibres are paralyzed. If such a patient were immersed in a cold bath and nothing more done, the circulation would be still more embarrassed; but if, in addition to immersing the patient, the body surface were subjected to friction, as it should be, the circulation would be greatly aided. He heartily indorsed what the reader of the paper had said about the harmfulness of leaving mechanico-therapeutics, and particularly hydrotherapy, to laymen. No physician would think of leaving the bathing of a typhoid patient to the nurse, except under the strictest supervision; yet it was exceedingly common for a physician to tell an individual afflicted with some chronic disease to "go and take some baths," or "get massage."

Dr. H. N. Vineberg said that in 1890 he had paid a visit to Brandt to study mechanico-therapeutics, and particularly pelvic massage. He would say at the outset that it was not necessary to spend half an hour or more in the treatment; indeed, Brandt himself treated upward of a hundred cases a day, so it was obvious that each treatment must have been short. Personally he was convinced of the great value of pelvic massage in a certain class of cases. Brandt had first recommended it in the treatment of procidentia, but had learned after a time that this was not the best field for its use.

Where Pelvic Massage is Useful.—The cases of procidentia in which it is beneficial were those of recent origin, and in which the pelvic supports were not greatly weakened. The other conditions of pelvic disease in which the treatment was useful were: (1) cases of chronic inflammatory adhesions; (2) cases of uterine displacement in which the uterus had not yet become retroflexed or undergone parenchymatous change; (3) pelvic exudates after the acute stage, provided pus was not present in any quantity; and (4) those cases of ovarian enlargement due to inflammation of the surrounding tissue. In cases of the fourth class, when the enlargement was the result of cystic disease of the ovary, the treatment was of no avail. The same remark applied to tubal disease, massage being beneficial only in cases in which there was thickening of the walls. It was better for the physician to treat these cases by the old tampon method than to resort to pelvic massage without being properly qualified for this special work.

Dr. Julius Rosenberg said that his experience with mechanico-therapeutics was chiefly confined to the pelvic organs. He had studied pelvic massage in Europe at one time, and in cases of old peritoneal adhesions had been convinced of the excellence of the results. In private gynæcological practice he frequently found retroversion of the uterus without any special laxity of the pelvic floor, and although these patients were usually ignorant of the existence of such a displacement of the uterus, they commonly complained of backache, weakness, and indigestion, and this continued even though the uterus were replaced and maintained in proper position by a pessary. These persons usually get out of bed late, lounge around the house most of the day, and, in short, have little or no exercise. These women are also usually in the habit of resorting to some method for preventing conception, and to this he attributed much of the trouble. It was in this class of cases that he had derived the most satisfaction from the employment of massage. Of course, it was necessary to insist upon a proper amount of exercise, proper diet, and habits of life, in addition to the massage.

Dr. Manley remarked that much had been said about prolapse of the pelvic organs—in other words, hernia—and he would only add that, as the operative treatment of hernia was rarely satisfactory, the importance of mechanico-therapeutics was obvious.

Dr. Gallant said that in the early years of his life he had been a firm believer in hydrotherapy, but had gradually degenerated into a prescriber of drugs. The reason was not that hydrotherapy had not accomplished a great deal, but because it was time-consuming and required special study.

Massage for Sprains and Intestinal Distention.—For four years he had studied the treatment of sprains by massage, treating, with Dr. Van Arsdale, over twelve hundred cases of this kind. He claimed that the patients had been cured in as many days as weeks were required by the old treatment. Many of them had been able to walk within an hour after receiving a sprain of the ankle. At the last meeting of this association he had spoken of the valuable aid abdominal massage had rendered him in treating intestinal distention and obstruction after laparotomy. In many cases of intestinal colic in infants, immediate relief would be afforded by massage of the abdomen. Further than this, he had employed pelvic massage quite extensively in gynæcological practice. It was true that he had not been able to make the uterus that had been prolapsed for some time stay up in the pelvis, but he had been able to relieve the pain produced by old adhesions or the symptoms resulting from various forms of uterine displacement.

Massage in Chronic Blepharitis.—Dr. Rose said all would admit the tedious and unsatisfactory nature of the usual treatment for chronic blepharitis, yet few seemed to be aware of the very gratifying and comparatively rapid results obtainable from gentle and systematic massage with an ointment.

Dr. McGillicuddy, in closing, said that a séance of fifteen or twenty minutes was usually sufficient for mechanical treatment.

Fallopian Tube and an Apendix after Operation.—Dr. A. E. Gallant exhibited the stump of a Fallopian tube, removed some time after operation. There was no ligature present, but the tube was not pervious. He also referred to a case in which it had been necessary to do a secondary operation on a patient who had been previously operated upon for a suppurative appendicitis. During the dissection at the second operation, he had found a very narrow band attached to the cæcum at one end and to the abdominal scar at the other. This proved to be the remains of the appendix, which had apparently been divided in the incision at the first operation.

Nominations.—*President*, Drs. J. Blake White and George T. Harrison; *Vice-President*, Drs. Frederick Holme Wiggin and Neil J. Hepburn; *Recording Secretary*, Drs. P. Brynberg Porter and M. C. O'Brien; *Corresponding and Statistical Secretary*, Drs. N. G. Bozeman and Parker Syms; *Treasurer*, Dr. John H. Hinton: *Executive Committee* (for four years), Drs. S. B. W. McLeod and J. E. Janvrin; (for one year) Drs. S. G. Cook and C. E. Denison.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 24, 1897.

WARREN COLEMAN, VICE-PRESIDENT, IN THE CHAIR.

Peritonitis without the Usual Symptoms.—DR. W. G. LE BOUTILLIER presented specimens from a case of supposed alcoholism and nephritis, in which the autopsy revealed an extensive peritonitis. He said that he was indebted to his colleagues at the J. Hood Wright Memorial Hospital for the specimens and the history of the case. The patient, a woman, twenty-nine years of age, had been brought to the hospital in the ambulance at 3 P.M. She had been found unconscious in the street, and so far as could be ascertained there had been no previous attack of this kind. Her general health had also been good. On admission the patient was profoundly unconscious; the pupils were moderately dilated and equal; the extremities were cold; the pulse was feeble, soft, and 70; respirations were 20; temperature was 99.2 F. in the rectum. The breath had a distinct odor of alcohol; the skin was dry and cold; there were no marks of injury on the face or body. The urine contained about fifteen per cent. of albumin. At 5 P.M. she could be aroused by frictions along the intercostal region, but did not respond coherently to questions. At 6:30 P.M. the respirations became gasping and the pulse imperceptible. In spite of the free use of heat and stimulants and the infusion of four pints of decinormal salt solution, the temperature was 94.6° F. at 8 P.M., and one hour later clonic convulsions developed, which involved chiefly the face, but also the lower extremities to a lesser extent. The convulsions were repeated at irregular intervals up to the time of death. By midnight the temperature had risen to 99.8 F., the pulse was 96, and the respirations were 20. The case appeared to be one of nephritis and alcoholism. At the autopsy general peritonitis was found, which was interesting in view of the low temperature and the absence of vomiting. The intestinal coils were distended with gas, and they, as well as the mesentery, were covered with a recent exudate. The bowel contained fluid fæces. The markings of the kidneys were distinct, and the capillaries, especially of the pyramids, were congested. The pelvic peritoneum surrounding the uterus and tubes was the seat of a recent exudate. The tubes contained a small quantity of pus. An examination of the brain revealed congestion of the pia mater and an acute meningitis over the left frontal and parietal lobes. The anatomical diagnosis was peritonitis, originating in septic salpingitis, probably following gonorrhœal vaginitis and endometritis.

Dr. Le Boutillier said that he had presented this case because of the absence of elevation of temperature and its important clinical bearings. Thus in many cases in which the diagnosis of appendicitis was clear, the presence of a progressive peritonitis was by no means certain. It was possible to have a general peritonitis associated with very slight pain and rigidity of the abdominal muscles, with a normal pulse, and without vomiting; yet the surgeon not uncommonly found that in a few hours the picture would be entirely changed, and on opening the peritoneal cavity a peritonitis would be revealed, which must have existed at first without the usual signs and symptoms. An important lesson to be drawn from the case presented was that it was not wise to consider coma and the odor of alcohol on the breath as sufficient grounds for a diagnosis of alcoholism.

DR. WARREN COLEMAN said that Dr. Buxton had told him of an autopsy that he had recently made, in which there had been marked changes in the kidney, but cultures having been taken from the various serous fluids of the body, the staphylococcus pyogenes aureus was obtained from the peritoneal fluid without any evidence of inflammatory process, either on the visceral or parietal peritoneum. The question therefore arose, whether this organism was not virulent in that particular case, or whether the resisting power of the peritoneum had been sufficiently great to prevent the pyogenic process.

DR. GEORGE P. BIGGS presented a number of miscellaneous specimens.

Fallopian Tube with Two Fimbriated Openings.—The first was a Fallopian tube with a double fimbriated opening—one at the usual site at the end of the tube; the other smaller and about one centimetre nearer the uterus. The specimen had been removed by operation from a woman, thirty-three years of age, because of a persistent salpingitis. There was slight, diffuse infiltration of all the layers of the wall with inflammatory exudate.

Gumma of the Liver.—The second specimen was a gumma of the liver, removed from an Italian laborer, forty-four years of age, who had died at the New York Hospital from a fracture of the skull. At the autopsy some gummatous deposits of unusual size were found in the liver. There were very thick adhesions over the site of these gummata, and the latter together formed a mass about ten centimetres in length and five centimetres in diameter. There was an old cicatrix at the inferior portion of the urethra, but no other lesions that could be considered distinctive of syphilis.

Heart Showing Large Fossa Ovalis and Open Foramen.—The next specimen, taken from a woman of thirty years, was a heart in which the fossa ovalis was of unusual size. In the fresh state it measured nearly 2.5 cm. in diameter. There was also a large, oval, membranous area in the septum between the auricles, sharply outlined; and at the anterior border at one point was a narrow, slit-like opening between the auricles, measuring about 0.75 cm. in the vertical direction. So far as known, there were during life no symptoms bearing upon the condition. Death was caused by acute arsenical poisoning.

Pancreatic Calculi.—The fourth specimen was a pancreas from a woman, forty-eight years of age, a seamstress by occupation, who had died from acute carbolic-acid poisoning. The pancreas was quite small, measuring 15 cm. in length, 1 to 2 cm. in thickness, and 1.5 to 3 cm. in width. The first inch of the duct of the pancreas was normal and pervious, but beyond this point a probe touched some calcareous material. On dissection a large number of calculi were found distributed throughout the course of the pancreatic duct. These measured from one to five millimetres in diameter, were rather irregular in outline, and many of them sent spine-like projections into the side of the duct. Numerous other calculi could be felt in the smaller branches of the duct, but were not exposed in the incision. There was very little pancreatic tissue left. At the tail of the pancreas was a cyst, about 2.5 cm. in diameter, fully distended with a milky fluid. The outer wall of this cyst was in such close relation to the spleen that the cyst was broken, and the contents were under such great pressure that they were forcibly ejected and so lost. It was not known whether any symptoms were produced by this condition during life. Dr. Biggs recalled having seen calculi in the pancreas in only one other case, and in that one there were only a few present.

Excessive Deposit of Fat in the Heart; Fat Necrosis; Hemorrhages in Other Organs.—The next specimen was a heart, taken from a woman, sixty-three years of age, who had given a history of numerous attacks of emphysema for a period of eight years. She had entered the New York Hospital in one of these attacks. She was so obese that the physical examination was very difficult. The heart sounds and

pulse were feeble: there was no elevation of temperature; there was general œdema, with indications of a moderate quantity of fluid in the peritoneal cavity. She became steadily weaker and died shortly after admission. At the autopsy the peritoneal cavity was found to contain six hundred cubic centimetres of straw-colored serum; there were numerous old pleuritic adhesions, together with general emphysema of the lungs and considerable acute œdema. The heart was presented because of the unusual deposit of fat in this organ. It was at least 1.5 cm. in thickness at the base of the right ventricle, and about 1 cm. in thickness at the base of the left ventricle. The heart was considerably enlarged; the cavities were moderately dilated; the valves were all normal. The muscular substance was of good color, but numerous deposits of fat could be seen scattered through the muscular fibres. The right side of the heart showed moderate hypertrophy. Microscopically the heart muscle revealed a considerable degree of parenchymatous degeneration and a moderate degree of fatty degeneration, chiefly in the form of infiltration extending downward in lines from the surface.

The pancreas from the same case showed an early stage of fat necrosis, with recent hemorrhages — an earlier stage than any he had before seen. The abdominal fat was excessive, yet there was no evidence here of fat necrosis. In the pancreas, however, the fresh section showed numerous small points of fat necrosis, and scattered rather diffusely through the pancreas were comparatively recent hemorrhages infiltrating through the pancreatic tissue. The pancreas was only very slightly enlarged. In the stomach, duodenum, and jejunum was a very extreme congestion of the mucous membrane, more marked in the two latter than in the stomach. There was fluid blood also in moderate quantity in the interior of these organs. There had been a number of hemorrhages from the mucous membrane, but there was no evidence of these having been brought about by any acute irritant. The congestion became less marked toward the lower part of the intestine, although all of the abdominal organs were considerably congested. In the stomach, along the summits of the rugæ, were numerous small superficial depressions, which at first glance suggested superficial ulcerations. Along the edge of these depressions were slight deposits of pigment, indicating that these were the sources of the hemorrhages. He had no explanation to offer for the existence of these hemorrhages.

Dr. Donald M. Barstow asked if in the first case there had been a corresponding condition in the other Fallopian tube.

Dr. Biggs replied that, as the specimen had been removed by the surgeon, he could not say.

Dr. Coleman asked how frequently the valve-like opening had been found in the heart.

Dr. Biggs said that he had seen it a number of times, but he did not think much leakage occurred through such a slit-like opening in the natural state of the parts. The case had been presented chiefly on account of the large size of the membranous area.

Dr. Coleman suggested that in the case of pancreatic calculi a fat necrosis might have been the starting-point. Fitz, he believed, had made the statement that these necrotic areas sometimes underwent calcification.

The society then went into executive session.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MEDICAL COUNCIL, DR. RENTOUL'S CLAIM—MR. HORSLEY ON REFORM, THE NEWSPAPERS AND HOSPITAL REFORM — UNIVERSITY COLLEGE — DR. SIMS WOODHEAD ON ALCOHOL—MAIDSTONE'S MEDICAL OFFICER—BELFAST'S EPIDEMIC—SIR WILLIAM MACKINNON'S BEQUESTS—THE LATE DR. BARRY, SIR A. C. BROWNLESS, DR. W. F. MURRAY, AND SURGEON-CAPTAIN MURRAY.

London, December 10, 1897.

Dr. Rentoul claimed expenses from the Medical Council in accordance with the standing orders as a member residing at a distance of above two hundred miles. The treasurers reported that the distance was only one hundred and ninety-eight miles. Dr. Rentoul made it two hundred and four, and says the distance from station to station is two hundred and one, which I have so found stated in the railway guide—a mode of verification which does not seem to have occurred to Sir D. Duckworth or Mr. Bryant (the joint treasurers): so they made a laborious calculation of the distance from the charge for fares, and of course were quite wrong. Nevertheless the council adopted their view and refused to pay the ten guineas due to Dr. Rentoul under its own orders. Surely it does not expect to atone for its extravagance in some things by such a mean thing as this? Dr. Rentoul presses his claim, but I am sorry he does so in terms that are certainly strong and even offensive. But this is hardly an excuse for resisting a just claim, and perhaps his indignation at the treatment he receives induced him to express his opinion instead of enforcing his right by legal process.

Now that the session is over and Mr. Horsley has done his work at it, he is not going to sit down and wait for medical reform. On Wednesday he gave an interesting address at the Southwestern Medical Society, on "The Medical Acts of Parliament: As They Are and As They Ought To Be." He confessed that concentrated action in administering the acts must be difficult until the constitution of the council is altered. He also pointed out that the legal advisers of the council had been obliged by reformers to change their views. Mr. Horsley's activity in reform is highly appreciated in all directions, *i.e.*, outside the council.

Hospital reform continues to be very much in the air—so much so that the newspapers are devoting attention to it. *The Times* has admitted a correspondence on the subject, in which Sir William Broadbent, Sir Henry Burdett, and Mr. Loch, of the Charity Organization, have taken part. The letters have been amusing to those who have been behind the scenes, but the taste and tact displayed in the controversy reflect no credit on the parties engaged. There are many who still put some confidence in the Organization Society, but the eyes of many have been opened and they have no faith in any scheme which will give the society power. This is what Mr. Loch aims at. He must seem to do something to earn his considerable salary, and his advocacy of a central hospital board means "Let my society control it." A central board may or may not be desirable, and there is room for free discussion of the point; but there can be no two opinions as to the danger of committing to the Charity Organization Society—that is, to Mr. Loch—the carrying out of any such scheme. The proposal it has circulated is cumbersome and, as Sir W. Broadbent has shown, absurd.

The munificence of Sir Blundell Maple in rebuilding University College Hospital may secure a fine

building, but in the mean time the hospital authorities are hard put to it to carry on the work. They have announced that they must sell their last investment and close fifty beds. If they do the college will no longer be a medical school, for the number will be below that required by the General Medical Council to qualify. This will be a sad blow to the college as well as the hospital. But perhaps some wealthy person may come to the rescue, or the public may refuse to let the hospital be so crippled.

I informed you that Dr. Sims Woodhead, the director of the research laboratories of our royal colleges, was elected president of the Medical Temperance Association, in succession to the late Sir B. Richardson. The new president seems likely to do good work for the temperance cause and not be a mere figurehead to represent the scientific aspect of the question. He lately read a paper to a conference of teachers in Dublin, in which he clearly showed them the present trend of medical opinion, and asserted that medicine would be in a better state to-day if alcohol had been interdicted for a century. In support of his views he quoted from an able address of Dr. Clouston's to the Edinburgh University students (1883). That eminent physician pointed out the many contraindications to the use of alcohol as a medicine, and pretty clearly indicated the wisdom of abstinence from its use as a beverage. Dr. Woodhead indorsed and advocated these views, and urged that in no circumstances should it be given when a desire for its continuance may arise. How near this is to prohibition may be judged from the cases which he mentioned as within the danger, for they include all in which the family history includes drunkenness, insanity, or nervous disease; persons who have used it excessively in early life; all who are nervous, irritable, or badly nourished; who have had injury of the head, sunstroke, or brain disease; who have great bodily weakness, especially in convalescence from exhausting diseases; who have exciting or exhausting work in bad air, as in workshops and mines; who are lonely or feel the want of amusement; who have little self-control or suffer from any brain weakness or senile degeneration. A full catalogue this, yet who would dare to except one of these as contraindications?

It is rather sooner than might have been anticipated, but the usual result of faithful service has come at Maidstone. The medical officer of health has reported that some of the more recent cases were due to direct personal contagion, while others were caused by drains and unflushed closets. This should be satisfactory in at least one way, for it shows that the water supply is now less dangerous. Upon this report a member of the board proposed a vote of dissatisfaction with the medical officer. I have not heard if the proposer is a holder of property in these defectively drained houses —it would not be in the least surprising. The resolution was withdrawn, but what a lesson its proposal affords! The water company and the board which supported its inaction would shift the responsibility of the epidemic on to the medical officer who early put his finger on the cause.

The outbreak of typhoid fever at Belfast will perhaps waken the local authorities to the urgent need of radical sanitary measures. A larger council has been elected as a result of the extension of the boundaries, and it is to be hoped that this "new broom" will "sweep clean." Probably the smaller body may have been impeded by property-owning members who dreaded the cost of sanitation. The zymotic death rate has long been abnormally high, but the local authorities did not take warning. The sanitary condition of the town has also long been a reproach. The new council will have its hands full in dealing with gross abuses, and if the outbreak of typhoid rouses the inhabitants to support stringent measures it will have helped to remove a constant danger.

The late Sir William Mackinnon, honorary physician to the Queen and formerly director of the army medical department, has left his fortune of about £25,000 for the advancement of science and scientific education. The Universities of Edinburgh and Glasgow are to have £2,000 each for these purposes, and after the payment of certain legacies and annuities the remainder goes to the Royal Society.

A memorial is to be raised to the late Dr. Barry, of the government medical department, of whose recent death I informed you. His colleagues and friends at first thought of limiting the movement to themselves, but it has been decided to accept any subscriptions sent but not to appeal for them.

Sir A. C. Brownless, who died on the 3d inst., was the founder of the medical school of Melbourne University, of which he was chancellor. He was also physician to the hospital. He received numerous honors, and at length our government recognized his position and gave him the K.C.M.G.

Dr. W. F. Murray, medical officer of health of Forfar, died on the 28th ult.; and Surgeon-Captain James Murray, of the Indian service, on the 8th ult., at Simla.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE BERLIN LIFE-SAVING SOCIETY—A NEW FACTOR IN THE DIAGNOSIS OF SARCOMA—THE FRANK COUPLER —DIAGNOSIS OF DIABETES FROM THE BLOOD—TREATMENT OF ŒSOPHAGEAL CANCER—VIRCHOW'S JUBILEE.

BERLIN, Dec. 15, 1897.

THE Berlin Life-Saving Society has just been organized under the direction of v. Bergmann, after the model of the Vienna Voluntary Life-Saving Society, which since its organization has proven of such great benefit. The Vienna society came into existence as a result of the awful Ring Theatre catastrophe, and has arrangements for immediate aid at large accidents, fires, ship or boat catastrophes, etc. The aid is voluntary and entirely free. v. Bergmann wants the same arrangement in Berlin; that is, the Berlin Society shall give first aid gratis, and then refuse further treatment, placing the patient in a hospital or turning him over to his private physician. In this respect it differs very much from the accident stations which have existed for two years in Berlin. They are located in all parts of Berlin, render assistance at all times in accident cases, but this assistance is not free. Either the patient himself or the society in which he is insured pays the bill. But the accident stations continue the treatment of the patient, either in the outdoor department or in the hospital; and therein lies the great evil of this system, for in themselves they serve to advertise a few surgeons and give to them at the same time a well-paying private practice. v. Bergmann skilfully avoided this dangerous reef in establishing the Berlin Life Society. He has therefore enlisted the sympathy of the Berlin profession, and with its aid, as well as the financial support of rich patrons, this humane institution is certain to prosper and to accomplish much good.

At a recent meeting of the Berliner medicinische Gesellschaft Dr. Rosin demonstrated a new diagnostic feature of the urine. A man, thirty-six years of age, had at the commencement of his illness much albumin in the urine; later, however, there was present propeptone (albumose) only to the amount of six per cent. The patient died, and the autopsy showed an amyloid kidney and multiple myelogenic sarcoma of

the ribs. A review of the literature of the past fifty years disclosed the fact that in the six reported cases in which propeptone existed in the urine the patients had either osteomalacia or sarcoma of the ribs. We may therefore regard a positive relation as existing between albumosuria and this class of sarcomata; perhaps it is permissible to regard this condition as diagnostic of sarcomata.

At the next meeting of the society, Dr. Frank, of Chicago, demonstrated his absorbable intestinal button, which has already been described in the MEDICAL RECORD.

At the Verein für innere Medicin, Dr. Loewy reported the results of his investigation of the discovery of Dr. Bremer, of St. Louis, that the blood in diabetes manifests peculiar properties toward the aniline colors. Loewy gave the matter a thorough trial, and agrees fully with Bremer that the blood loses markedly its property of taking on the colors. For instance, with eosin the red blood cells take on a brownish color normally; in diabetes a greenish-yellow.

Professor Rosenheim reported a new therapeutic measure for œsophageal carcinoma. It is dangerous to relieve the dysphagia and choking sensations of these patients by means of the tube or sound. Furthermore the neoplasm is thereby irritated and more pain is given to the patient. The increased irritation produces a spasm, thus increasing the difficulty of swallowing. One patient could swallow nothing on account of the spasm, but after a morphine injection could swallow all foods. Rosenheim has attempted by means of a specially constructed spray, which enables him to apply slightly caustic solutions directly to the diseased area, to diminish the symptoms. Among a number of different fluids he recommends these as of special benefit: solution of nitrate of silver, two to five per cent.; or eucaine in three to five per cent. solution. The spraying is carried out morning and evening at first: later less frequently. In a number of cases the difficulty in swallowing was considerably relieved. Rosenheim also reports good results from galvano-cauterization with the porcelain burner.

At a meeting of the Berliner medicinische Gesellschaft, Professor Senator delivered a congratulatory address to Professor Virchow, the Nestor of medicine, and for many years president of the society, it being the fiftieth anniversary of his career as a teacher. With appreciative words Virchow thanked the speaker. He reminded those present that the Berliner medicinische Gesellschaft was also celebrating its fiftieth-year jubilee, and he wished it in the second half of the first century of its existence an ever increasing prosperity and a continuation of its never-ceasing efforts to broaden medical science and promote the dignity of physicians.

THE CHEAT OF CHARITY.

To the Editor of the Medical Record.

SIR: It gave me great pleasure to see that you had the courage editorially to denounce the donation of public funds to private medical institutions. My only regret is that you did not make your denunciation more specific and scathing.

The chief culprits we all know are those hospitals and dispensaries which also teach students or practitioners of medicine.

Once a year, as appropriation day comes around, they come to the front with extended palm, posing as charitable institutions. It is this act of duplicity which condemns them. They are not charities in any sense of the word. They were founded primarily to give a few men titles and a teaching position; secondarily, to give undergraduate or post-graduate instruction in medicine. Incidentally also in order to get clinical material for their lectures, they treat gratuitously a great number of patients, many of them totally undeserving.

The dispensation of charity was not primarily an incentive in the foundation of most of these institutions, nor is it to-day an ingenuous pretext for their maintenance. Their boasted charity is no charity.

In the first place, a poor patient who, in return for free treatment, gives freely of his time and comfort to the cause of medical education repays his obligation, generally fully and often with interest. Submission to demonstration and examination by numerous students, few of whom are either gentle or skilful, in itself often entails a sacrifice of time, comfort, or modesty which repays for the favors granted.

In the second place, the students generally pay directly or indirectly for these privileges, and these fees again help to wipe out the debt that charity entails.

In the third place, while not designed for but while pretending to dispense charity, they claim municipal reimbursement for free services already nearly or quite paid for. Charity which is paid for is no charity, and let us hear no more of this specious cant.

Had the good Samaritan, who stanched the wounds of the man who fell among thieves, hunted up the board of apportionment of Jericho and demanded to be reimbursed for the oil and wine he poured in the traveller's wounds and for the bandages with which he bound them, methinks his name would not stand to-day as a synonym for noble goodness, but rather for tricky evil, like that of Judas or Ananias.

ROYAL W. AMIDON, M.D.

72 WEST FIFTY-FIFTH STREET, NEW YORK CITY.

TO ABATE THE DISPENSARY EVIL.

To the Editor of the Medical Record.

SIR: In your issue of November 27th I note reference to the New York Cancer Hospital, with the reproduction of a circular letter which it sends to the physician of all patients who apply at its clinics for free treatment. Your comments were favorable as to the idea. Permit me to call your attention to a similar letter which has been used by the Chicago Eye, Ear, Nose, and Throat College for several months prior to the adoption of the idea by the New York Cancer Hospital. I herewith inclose copy of this letter, bearing date March 26, 1897, which was the time when first issued. Should not we have the credit of being the originators or at least the first to put in practice this idea for discouraging clinical pauperism?

EDWIN PYNCHON, M.D.

CHICAGO, ILL., December 13, 1897.

"CHICAGO, ILL., March 26, 1897.

"*Dr.*.....

"DEAR DOCTOR: M..... has applied to us for treatment as a charity patient, and has given your name as having been the former medical attendant. We have been led to suspect that this patient is not entirely unable to pay, and hence is not entitled to free treatment, which it is our aim to extend only to the worthy poor.

"Do you consider the above-mentioned patient as being one entitled to free treatment?..... We will consider this communication as strictly confidential. If not a worthy poor patient, will decline to extend further free treatment, and refer same to you.

"Yours very truly,

"CHICAGO EYE, EAR, NOSE, AND THROAT COLLEGE."

MERCURIC CATAPHORESIS FOR SARCOMA.

To the Editor of the Medical Record.

Sir: In a summary of the scientific work of the Philadelphia County Medical Society at a recent meeting, which appears in the Medical Record for November 20th last, page 745, I am reported as having presented a patient who had been cured of a "large swelling" of the upper jaw by the mercuric-cataphoresis method. This description of the nature of the tumor was a grave injustice to scientific fact, as I stated that there could be no doubt whatever that the tumor was sarcomatous, it having been so diagnosed by a number of reputable physicians, including two of our most prominent surgeons, who advised the immediate extirpation of the superior maxilla in an effort to remove it. It is important that the results in this case should be properly understood, since it proved that a sarcoma of large size in this situation could be destroyed in a few weeks by one or more massive applications of the electro-mercuric process with gold electrodes, the patient being etherized. The cavity that was produced has nearly filled up with healthy tissue.

G. Betton Massey, M.D.

Philadelphia, December 12, 1897.

AMERICAN MEDICAL STUDENTS IN GERMANY.

To the Editor of the Medical Record.

Sir: In the Medical Record of November 6, 1897, in the Berlin letter, page 684, stands the following in regard to foreigners studying medicine in Germany: "It has been ruled that only such persons as have passed the preparatory medical examination in Germany, or one similar thereto in other countries, may be admitted to visit and study at the clinics, etc. As a degree from a German college (gymnasium) is required of all candidates for the *testamen physicum*, and as there exists in America no arrangement corresponding to the German *physicum*, the importance of this new law is very apparent, for it excludes Americans from clinical studies in the German States."

In the *Veröffentlichungen des kaiserlichen Gesundheitsamtes*, Jahrgang xx., Nummer 47, November 18, 1896, Seite 888, appears the following order from the Prussian minister of public instruction, undoubtedly the ruling referred to in the above quotation: "In the interest of a uniform course of medical study, I hereby decree that students may first be admitted by the directors to practise in the university clinics and polyclinics, after they have fully completed the preparatory medical examination within the German empire, or a corresponding examination elsewhere."

In this same publication, Jahrgang xxi., No. 35, September 1, 1897, S. 710, are communications from the departments of public instruction, etc., of Bavaria, Saxony, Würtemberg, Baden, Hessen, Mecklenburg-Schwerin, Saxon-Weimar, and Elsass-Lothringen, all of which are formal acceptances of the above order of the Prussian ministry, and all of which read: "No students shall be admitted to practise [zum praktiziren] or as practitioners [als Practikanten] in the clinics, etc.—the same to go into effect with the beginning of the present semester.

Notice the words "to practise." The custom in the clinics here is this: The student enters his name as a "Practikant," or as an "Auscultant;" the professor takes the list of the names of the Practikanten into the clinic and calls therefrom, each day in turn, a student to the table, there to examine the patient, answer questions, etc., while the others, Practikanten and Auscultanten, see and hear. The second class of students—Auscultanten—is privileged to visit and study at the clinics, but its members are not thus called forward. A foreigner, with his imperfect mastery of the German language, rarely enters his name as a Practikant. Indeed, Dr. Gaffky, director of the Institute of Hygiene of the University of Giessen, to whose kindness I am indebted for the above references and explanation, tells me that never in his experience has he known of a foreigner studying as a Practikant.

In view of the above, I conclude that an American may visit and study at the clinics of the German universities as he has always done, *i.e.*, as an Auscultant; that the new ruling prohibits him only from studying as a Practikant, which he has never done; that it prevents in no way the admittance by the directors of any student to the hospital wards, etc.; and that the rule is not a discrimination against foreigners, especially Americans, but is intended to insure a more uniform course for the German student.

Having had ample opportunity to experience the genial hospitality and the friendliness of the Germans toward an American, I have written the above in the hope of aiding to dispel the idea, apparently gaining ground in America, of discrimination against and exclusion of Americans.

J. Edwin Sweet, A.B.

Institute of Hygiene, University of Giessen, December 6, 1897.

A THEORY AS TO THE PRODUCTION OF RASH IN ANY OF THE EXANTHEMATOUS DISEASES.

To the Editor of the Medical Record.

Sir: During an epidemic of scarlet fever at this point, there came under my notice a number of cases of jaundice, due to a catarrhal obstruction of the common bile duct. The discoloration of the skin was well marked, and it seemed from the number of cases presenting themselves that we had what might be called an epidemic of jaundice.

Seeing so many of these cases developing during the run of scarlet fever, I began to speculate as to the possible connection between the two diseases, but I could arrive at no satisfactory conclusion as to the one having any bearing upon the other. This thought, however, occurred to me, and I hope that it may be the cause of investigation upon the part of some one more favorably situated than I am.

Following up the well-known theory as to the causation of skin pigmentation in jaundice and the distribution of bile pigment in the different tissues through the medium of the blood stream, I evolved the idea that possibly the rash in measles, small-pox, scarlet fever, and other microbic systemic diseases having a localized or general epidermal manifestation, might be caused by the deposit in the skin, during its efforts to eliminate it from the body, of some portion of the secretion of one of the eliminating or digestive organs—these glands, because of the specific organism which produces the disease, either secreting an abnormal by-product or an amount of normal secretion in excess of the demands of the system.

The blood stream, acting in this emergency as it does in the case of catarrh of the bile duct, distributes the altered secretion throughout the economy, that the skin and all the eliminating organs may help to excrete it.

If my theory is correct, the treatment of these diseases resolves itself into the discovery of the organ involved in each of the different manifestations, and directing the treatment to it, either as to counteracting the pernicious action of the specific micro-organism upon its stroma or its secretion, or introducing into the system some substance which will for the time be-

ing reinforce the diseased gland or mitigate or destroy the action of its altered secretion.

It may be possible that the high mortality, the paralysis, nephritis, deafness, loss of sight, and many other pernicious manifestations which follow in the wake of the exanthemata may be due, not to the action of the specific micro-organism, but to the poisonous effect of an alkaloid secreted by some organ, diseased because of the action upon it of the germ which produced the malady. Immunity might be explained under the theory that the abnormal secretion inoculates the system against the further invasion of a given micro-organism.

I hope that some one better able than I am may take up this question and investigate as to the possibility of the theory being correct.

W. V. Gage, M.D.

McCook, Neb., December 3, 1897.

"ONE MORE KICK AT AN ABUSED PROFESSION."

To the Editor of the Medical Record.

Sir: In the Medical Record of November 13th there is an editorial, "One More Kick at an Abused Profession," in which you note the decision of the Illinois court of appeals in the case of Dr. Dixon, who was compelled to give expert testimony without a fee. I find an editorial on the same subject in the *New York Law Journal* of December 3d, in which the opinion of the Illinois court is upheld—that expert witnesses have no right to refuse their expert opinions. The subject is, however, one entirely under the control of the expert witness. Every witness is by the common law obliged to answer that which he knows, when all knowledge is one of facts. If the medical witness is asked a question in medical science the answer to which he absolutely knows, he has no legal right to refuse an answer. But when the expert is given a state of facts, as embraced in a hypothetical question, the witness does not know the answer until he proceeds to labor mentally, and, as the result of such labor, gives his conclusion. The medical witness has as much right to refuse to labor (mentally) for the court as a carpenter has who refuses to construct a stairway for the accommodation of the judge. All that the medical witness has to do is to discriminate between scientific facts which he knows and opinions asked for upon such facts. He must answer the first; he is not bound to answer the second.

R. L. Pritchard.

MIDWIFERY AND THE MIDWIFE.

To the Editor of the Medical Record.

Sir: Allow me to add a word in substantiation of the article of Dr. Van Ramdohr in a recent issue of the Medical Record. It is the physician who practises in the crowded districts who is called in to correct the mistakes of these ignorant and unscrupulous midwives.

One morning in June last I was called in a hurry to see a woman who was in labor. On my way to the house I was told that the woman was the mother of six children, and that her husband was away in Africa. When I arrived at the house, the building was in an uproar; women were standing on the stairs and lamenting the fate of the poor unfortunate woman, who had been in labor more than twenty-four hours. One who was more talkative, and proved to be the midwife in the case, said she could not account for the delay in the birth of the child, as she had never before had a failure in her practice. This impressed me at once that her experience was very limited, and I proceeded to examine the patient. The appearance of the patient was enough to inspire fear as to the result. Her legs and vulva were œdematous; the heart was dilated. One woman said that the patient had convulsions a few hours ago, but that nobody paid any attention to them. I was washing my hands in order to make a vaginal examination, when the midwife, who was fanning the patient, gave a cry, and on going to the patient I found she had expired.

Now this is one of the many cases that come under the notice of the physicians in the tenement districts. Had medical attendance reached this woman in time, one if not both lives would have been saved. As a rule, most of these midwives have too much confidence in themselves. It is nothing strange to meet midwives who have had other occupation previously, and by chance become midwives. If every doctor would report such cases occurring in his practice, enough indignation would arise, and a law regulating this delicate art would be enacted. Until a law regulating the practice of midwifery is enacted, the lives of mothers and babies will not be safe.

M. Ghertler, M.D.

126 Rivington Street, New York.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 25, 1897:

	Cases.	Deaths.
Tuberculosis	213	90
Typhoid fever	17	7
Scarlet fever	165	8
Measles	289	9
Diphtheria	163	26
Laryngeal diphtheria (croup)	6	0
Chicken-pox	35	0
Small-pox	1	0
Cerebro-spinal meningitis	1	6

Rupture of the Aorta "in a fit of anger" is reported from Paris, and should prove a warning to all who permit their passions unduly to rise, especially if plaques of atheroma are suspected to exist.

Freezing is advocated by Bujwid as a method of concentrating animal serums. The upper layer, upon slow thawing, is a watery fluid without value, while the lower contains the concentrated antitoxin.—*Centralb. f. Bakteriol.*

Lead Poisoning has recently been reported from the use of a patent medicine, which was found on analysis to contain the drug in large amount; and in another instance from too free indulgence in paprika, which had been adulterated with red oxide of lead.

Lengthening of the Diastolic Interval in certain forms of cardiac disease is of grave moment, according to Huchard, and its early discovery may lead to measures intended to prevent dilatation. Digitalis should be withheld.

Criticism has been freely bestowed by the daily press upon a physician of this city who declined to respond to a night call from a grocer who had refused to pay his doctor's bill. Perhaps some time the public will learn that a good way to make sure of timely medical attention when needed is by paying for what it receives as it goes along.

IMMUNITY: RECENT THEORIES VIEWED FROM THE CLINICAL STANDPOINT.[1]

BY W. GILMAN THOMPSON, M.D.,

NEW YORK.

THE astonishing results obtained within the past two or three years from sero-therapy and sero-diagnosis must necessarily tend to modify previous theories of immunity from infectious diseases, and it is the purpose of this paper briefly to review the subject from both the theoretical and the clinical standpoints.

To the original broad division of immunity into (*a*) the natural and (*b*) the acquired forms, must now be added (*c*) the artificial type—for of immunity, as of greatness, it may be truly said: "Some are born immune, some achieve immunity, and some have immunity thrust upon them." In seeking a comprehensive explanation which will embrace the greater number of its phenomena, one finds two dominant views in the literature of the day, which have quite supplanted older theories. These are: (1) The influence of the phagocytes, either as devourers of germs or producers of substances which destroy germs or their products (toxins). (2) The influence of antitoxins, either as chemical antagonists, acting by neutralization of toxins, or as physiological antagonists, acting by stimulating the cells of the body to increased resistance.

Other theories there are in abundance, but the present tendency is to forsake them for the newest teachings of the laboratory, which, for the time at least, threaten to divert attention from due consideration of clinical data. This has been the fate of the theories of Chauveau and of Pasteur. Chauveau held that immunity is due to accumulation of waste products, poisons, the result of germ action, which overwhelm the source that developed them, very much as alcohol in time destroys the yeast fungus which produced it. The permanence of retention of such waste products within the system should determine the duration of immunity.

Pasteur, on the other hand, taught that immunity is due to exhaustion of a special pabulum or germ-growing soil within the body—practically a soil sterilization—which soil is not renewed after infectious diseases, in which, as in measles, immunity is acquired after a first attack, but is renewed in time in diseases which, like pneumonia and erysipelas, confer no definite immunity.

It will be observed that neither of these two theories comprehends any vital action of tissues or of cells other than that of the germs themselves, and both are much weakened by such a demonstration as the fact that anthrax bacilli may still live in the serum of animals which have acquired complete immunity against them.

Yet another theory, which has been strongly advocated by Calabrése[2] and others, is that the alkalinity of the blood increases with the degree of immunization, and causes it: and in direct opposition is the theory of Roux, that an excess of nucleinic acid is developed, which either neutralizes the toxins or is bactericidal.

Turning to the two major theories of the influence of the phagocytes and of the serum, so much has been argued both for and against them that they should be examined in detail.

The theory of immunity through phagocytosis, *i.e.*, of the germ-devouring action of certain voracious leucocytes, as elaborated by Metschnikoff and his followers, at first seemed as plausible as it is ingenious. This bacteriologist showed that under certain conditions cholera vibrios injected into the peritoneal cavity are promptly converted into inactive granules by the leucocytes (phagocytes). Bardet[3] adds his testimony that preventive serum has the effect of directly stimulating leucocytes to devour cholera bacteria *in vitro*. Mesnil[4] proved that anthrax bacilli in the peritoneum of a fish (perch) are eaten by phagocytes. The serum of immunized animals, while protective, is not necessarily bactericidal, and tetanus spores, washed free of toxins, when inoculated in animals, are devoured by phagocytes.

This restricted view of the function of leucocytes, as destructive of germs by devouring and digesting them, has not withstood the test of further experimentation, and it has been largely modified and replaced by the theory that the leucocyte acts not as a phagocyte, or devourer, but by developing and secreting substances which are inimical to the germs, and which may affect them even at a distance from the body of the leucocyte.

As opposed to the purely phagocytic theory is the fact that in mouse septicæmia the bacilli are known to multiply within the leucocytes. Sometimes the latter are so overcrowded as to make it impossible for them to have eaten all the contained bacilli, yet other phagocytes among them contain no bacilli (Sternberg[5]). The presence of gonococci within leucocytes led at first to the belief that they had been devoured, but it is now known that the germs die from other causes, and are subsequently taken up by phagocytes which act as scavengers, very much as they devour old products of inflammation, pus cells, granular detritus, inhaled carbon, pigment such as cinnabar used in tattooing, and even such tissues as those of the tadpole's tail at the time of absorption.

From a physiological standpoint substances must be regarded as still outside of the organism until they have entered the blood, lymph, or tissues, even though they are anatomically within the air passages or alimentary canal. It is certainly characteristic of many of the most severe infections in which the germs have been demonstrated that the latter remain for the most part outside of the body, physiologically speaking, although they may be found at times in the blood or viscera. This is true of the typhoid, diphtheria, cholera, pneumonia, dysentery, and many other bacilli: and this fact renders them much more independent of the attacks of phagocytes whose special territory they

[5] "Immunity and Sero-Therapy."

do not invade. The phagocytes may gather to prevent such invasion at any definite point, but neither there nor on the free surfaces are they found in number proportionate to the germs present. Hence it is clearly impossible for them to cause immunity by phagocytosis in such instances, although it may be admitted that exceptionally, where the germs tend to invade the blood or viscera, there may be something of a battle royal between leucocyte and bacillus. Even in such cases, is it not possible that the leucocyte first kills the germ at a distance by means of some secretion, and then devours it as a foreign body? The dead or inactive bacilli have been found in some infections, not within, but near the leucocytes, as in Nuttal's experiments with anthrax bacilli inoculated in the rabbit's ear. Vaughan, McClintock, and others believe that the leucocytes supply a nuclein, soluble only in alkaline fluid, which is a protective agent: and Sternberg is disposed to regard natural immunity as due to a substance in the serum derived from leucocytes and also soluble only in an alkaline medium, infection being combated by both the leucocytes and the alkalinity of the blood.

The phagocyte, when about to lose prestige as a germ destroyer, has been rescued again by the hypothesis that it fulfils the rôle of either a ferment producer or an antitoxin manufacturer, the latter action being in all probability induced by the agency of a ferment derived from the leucocyte and acting upon the proteids of the blood serum. The phagocyte is, after all, but a unicellular organism of a low order of development, and although endowed with some remarkable properties, like its recognition of or attraction toward irritants such as bacilli, and its capability of being "trained" to increasing powers of resistance, it is nevertheless expecting far too much to suppose that it can manufacture offhand a specific antitoxin to neutralize all the specific toxins of some forty infectious diseases. Of all the adaptations by nature of organs or organisms to resist external irritants, there is no analogy to such a phenomenon. To avoid so untenable an assumption, Reid,[1] in a recent very able article upon immunity, holds that the phagocyte secretes an enzyme, a single digestive body, which is capable of digesting and thereby neutralizing all manner of toxins, just as a single ferment, pepsin, digests a variety of proteids—globulins, albumoses, etc. Such a ferment is rapidly formed, and, he says, "it is probable that the digestive substance produced by the cells is normally present in them, but that its secretion is greatly accelerated by the presence of certain foreign bodies in the blood—*e.g.*, bacteria and their toxins." He supposes that the blood holds toxins in all stages of digestion, that the stronger toxins are not necessarily of identical composition with the weaker, and that the weaker toxins may act meanwhile as immunizing agents, thus producing an acquired immunity, which he defines as "an habituation of the cells concerned to the toxin, as a result of which their phagocytes are able to destroy the pathogenic micro-organisms producing it," and "the cells concerned are able to perform their functions in spite of the presence of toxins."[2] He further claims that immunity exists only against those diseases which produce powerful antitoxins, whereas in such diseases as tuberculosis, lacking immunity, the germs destroy the phagocytes. In other words, immunity is in direct proportion to the quickness of production of the original toxins and their stimulating effect.

To consider now the blood-serum or antitoxin theory of immunity, it would appear, in so far as it is applicable, to be capable of much more absolute proof than either of the others. The greatest medical question of the day is to what extent we are to be able to utilize and rely upon it. Is it destined to exclude all other theories of immunity? Is it therefore destined to become of general application to all infections? Is the artificial immunization through serum antitoxins as strong and as enduring as are other forms? Must we confine our views to any one theory?

The poison of any infection must necessarily pass through the blood or lymph in order to reach the body tissues generally: hence it is a distinct gain, both in point of time and substance, to have its action neutralized in the blood serum. The "resistance of tissues" is, after all, a somewhat vague phrase, and any definite knowledge of how to increase this resistance artificially, and thereby produce immunity, is lacking. The phagocytosis theory deals with the germs rather than their toxins. The toxins may have been formed before the phagocytes can act, and, moreover, we possess no reliable means of producing immunity through stimulation of phagocytosis. The theory of exhaustion of the soil in which the germs grow presupposes the complete development of the infection. But serum which is antitoxic, whether so rendered artificially or naturally, is the ideal immunizing agent; for it is independent of tissues, it is universally present in the body, and before either phagocytosis or soil sterilization or exhaustion has time to act it opposes the toxin as fast as formed, so that, as for example, in diphtheria, the antitoxin practically cures the disease and immunizes the patient long before the bacilli have left the throat. The blood serum, which is the chief transmitter of infection, thus becomes its chief antagonist. From the data thus far accumulated, however, it would appear that artificial antitoxin immunity is not so strong or so lasting as natural immunity, thus rendering reinoculation desirable in time of exposure. This is true even of small-pox and vaccinia. No one would think of the revaccination of a patient who had had a typical attack of small-pox, for immunity is practically permanent. W. M. Welch[3] says that "no person during the last quarter of a century has been admitted to the Philadelphia Municipal Hospital twice suffering from the disease."

Yet we know that the immunity against variola produced by vaccinia (which is in all probability due to an antitoxin formed in the blood after inoculation with this latter disease) must, in order to become permanent, be renewed several times after intervals of a half-dozen years. The artificial immunity established by inoculations of tetanus antitoxin, diphtheria antitoxin, antistreptococcus serum, etc., is far from permanent. A protective inoculation of three hundred diphtheria antitoxin units confers immunity in man of but from three to eight weeks (Park[2]). Paterson,[3] of Glasgow, procured artificial immunity in fowls from fowl tuberculosis which persisted for only five months. Powell,[4] in a summary of all the published experiments in India in anticholera inoculations, concludes that doses large enough to occasion decided febrile movement seem to confer immunity, but that smaller doses confer very brief if any protection.

Attractive as is the question of immunity by antitoxins, it yet leaves many facts unexplained. It of course does not account for natural or congenital immunity in distinction from that conferred by a single attack of an infectious disease. During the prevalence of an epidemic, doubtless many persons escape infection merely because the specific germs do not happen to find entrance to the body at a propitious

[4] Lancet, 1896, No. 3,803, p. 169.

time for their development. For example, Netter found the pneumococcus present in fifteen per cent. of normal mouths. The gastric juice may be strongly acid when cholera germs are swallowed, thus destroying their virulence; there may be no abrasion of the throat at the time when diphtheria bacilli are present or no tegumentary lesion to admit the virus of syphilis, leprosy, or erysipelas—yet those who thus happily escape through such chances are by no means immune. It is a common experience for persons to pass through several epidemics of yellow fever or influenza without infection and yet eventually to succumb, even when there is no appreciable difference in their general state of health. Thus immunity is often apparent rather than real, and is therefore far less general than is supposed.

The difference shown in regard to the ages of individuals at which the various infections are most easily acquired would seem to point rather to inherent tissue resistance than to inherent protective qualities of the blood serum (antitoxins).

Doubtless all the softer parts of the body are undergoing constant and more or less rapid and complete chemical if not structural renewal. It is easier to conceive of the cellular structures of the body transmitting either natural or acquired resistance to infection from one cell generation to another, than to believe in the permanence of an antitoxin in the blood serum. Of all tissues the blood undergoes most rapid and frequent change. The life of many of the corpuscles cannot exceed a few hours, or one or two days at the most. The red discs are constantly being destroyed to furnish biliary and other pigments, and the leucocytes fluctuate greatly in number, corresponding with as simple a varying condition as the amount and quality of food eaten. The blood serum is the fluid from which all the digestive fluids and many others, amounting to many quarts daily, are replenished, from which all the liquid secretions are derived, and in which all the varying quantities of food derivatives and of waste must sooner or later circulate. The blood, moreover, as a whole, has a remarkable tendency to maintain a uniform composition and to rid itself of accidental ingredients. An antitoxin is certainly not a normal ingredient of the blood, but rather a product of special and temporary chemical, fermentative, or other action. Methods of preparation of antitoxins outside of the body prove this. How, then, are we to conceive of prolonged immunity from a specific infection as produced by an antitoxin? Does the antitoxin perpetuate its own kind by renewal? This is contrary to experimental results. Does it stamp an imprint upon the blood serum as a whole? But this highly complex serum is constantly varying in its ingredients, while yet maintaining an average uniformity in composition. One cannot readily conceive of it as subject to laws of heredity. It must therefore be so often renewed that it is difficult to believe that an antitoxic serum—practically a foreign substance—can long remain in it. There are, however, one or two recent observations which appear to argue for the permanence of an antitoxin once formed in the serum. For example, Vailliard has shown that in the case of a rabbit immunized against tetanus, and then bled until half the volume of its blood is withdrawn, the remaining serum is subsequently found to be just as strongly antitoxic. The agglutinating substance, or "agglutinin" (Gruber), of typhoid-fever serum may persist in the blood for five or six years after the fever, and although this is not, strictly speaking, an antitoxin, its prolonged retention in the serum is a very significant fact.

The final *modus operandi* of antitoxins in the serum is still open to question. The theory that it is by neutralization of the toxins in any chemical sense is scarcely tenable, although the laboratory experiments in the case of diphtheria might favor this view. The exactness with which a guinea-pig can be given a definite lethal dose of toxin and then be saved by a definite dose of antitoxin is demonstrable with almost mathematical accuracy, yet it is difficult to conceive that vaccine virus can cause any chemical neutralization in the extremely minute quantities in which it is employed; and if the relatively small immunizing dose of diphtheria antitoxin—three hundred units—acts by chemical neutralization of toxins as fast as they may be formed in a fresh infection, the dose might be readily exhausted before all danger was passed.

Buchner thinks that the toxin and antitoxin do not neutralize each other, but that both act antagonistically upon the cells of the organism, somewhat perhaps as atropine antagonizes morphine, by counteracting its influence upon the nervous system, and not at all by chemical interaction. He found that tetanus antitoxin and toxin in mixture might prove harmless to one animal, and yet virulently poisonous to another. Obviously this would be impossible if chemical neutralization had been produced. Still another argument against such neutralization is that of the experiments of Roux and Vailliard: the serum of the horse is rendered antitoxic against tetanus if the tetanus toxin be injected, but if the process is conducted too rapidly or if too large doses are injected, the serum loses its antitoxic property wholly and becomes toxic. Reid believes that the cells in this case cannot digest the toxin fast enough to immunize the serum.

Grubner,[1] of Vienna, after experimenting with cholera, typhoid, and colon bacilli, concludes that the immunizing substances of bacteria themselves are not identical with bacterial toxins. In other words, animals may be proof against bacterial infection, but yet not toxin-proof. He regards the polynuclear phagocytes as playing "a comparatively unimportant part in the process" of destruction of bacteria, and thinks that the essential immunizing substances are those which make the bacterial walls adhesive and their sheaths more penetrable to the alexins or germ poisons, which then enter and destroy the germ protoplasm. The agglutinins are themselves exhausted in the process; hence the limitations of immunity. He claims that each bacterium has its own peculiar agglutinin (a complex theory, surely!), which is produced from itself in the body of an actively immune animal, by combination with some substance furnished by that animal. Durham maintains that the agglutinin acts directly on the germ, without reference to its protective sheath. (The recent experiments of Koch with tuberculin T. R. are interesting in this connection, as showing what may be derived from bacteria after destruction of their protective sheaths.)

That the blood serum may contain two different substances—one bactericidal, the other antitoxic—has been repeatedly demonstrated in special cases. Klein, for example, showed that when pure toxins are injected in the horse, the serum increases in antitoxic power, but loses in germicidal effect. If, on the other hand, the bacilli themselves are injected into the serum, the reverse obtains.

According to Buchner, the blood resists infection by development of two distinct kinds of protective substances: (1) alexins, which are germicidal proteids, of general character, without specific action, and universally present in all animals which are either actively or passively immunized. They are destroyed by lower temperature than the second class of substances, known as (2) antitoxins. These are not germicidal, but antagonize the effect of the toxins upon the cells and tissues of the body.

[1] Max Grubner: Lancet, October 9, 1897, p. 910.

To the alexins belongs natural immunity; to the antitoxins belong acquired and artificial immunity.

Any attempt to bring the manifold phenomena of immunity under one comprehensive theory must involve a solution of the two queries:

1. Is natural immunity in man different in kind from that which is acquired by a first attack?

2. Is natural immunity of a wholly different origin from that which is artificially induced?

The first hypothesis may be controverted by known laws of heredity and survival of the fittest. The Japanese rarely have scarlatina. Syphilis and gonorrhœa are mild among them. Negroes are less often than white men affected by enteric fever and yellow fever, yet they are very susceptible to variola and syphilis. The natives of India are often (though not always[1]) immune to enteric fever, yet they are highly susceptible to cholera, the bubonic plague, etc.

Even more remarkable instances of exemption occur among animals of the same species; thus Algerian sheep, like carnivores, are immune to anthrax, while other varieties of sheep are most susceptible to it (Sternberg[2]).

Must it therefore be supposed that in the serum of one man there exists a natural (congenital) antitoxin for one disease, and in that of another man for a different disease; or that the phagocytes of one man possess natural powers not given to those of another? Is it not more reasonable to believe that so-called "natural" immunity is really acquired immunity, but which has been acquired in previous generations that have been attacked by an infection which has proved fatal to the most susceptible, and has left the tissues of the survivors more resistant, and that this increased resistance has been transmitted by heredity? The possibilities of the transmission of hereditary immunity from syphilis and small-pox have long been recognized. H. Batty Shaw[3] has lately reported the observation of the Widal reaction in the blood of an infant whose mother had just recovered from enteric fever, which attacked her while the child was *in utero*.

If this view be correct, then natural immunity is a misnomer, in the sense that the individual or his ancestors never under any circumstances could have had a certain infection, and all immunity becomes originally acquired and transmitted until by intermarriage it may become weakened or lost. In any event there seems no compulsion to the belief that "natural" immunity is of a different nature or character from that which is acquired as a result of actual infective processes.

Is artificial immunity to be differentiated in kind from that which is acquired? If it be due to the substance inoculated acting as a neutralizer or antagonist to the disease toxin, as the acid neutralizes the base (v. Behring, Fraser) or the chemical antidote the poison, then, having done its work, it should be of no further use, and, being in reality a foreign body, it should be eliminated in time as completely as a dose of potassium iodide. But this explanation fails in accounting for any degree of permanence in artificial immunity. There seems to be some doubt, however, as to whether such permanence is really attainable from a single dose or series of doses of an antitoxin, as it may be through actual acquirement of the infection itself. This phase of the subject is as yet too recent to admit of accurate conclusions.

Critical study of the numerous and diverse methods of producing immunizing agents throws but little light upon the problem of the permanence of immunity in man. Briefly, immunizing agents may be produced by any of the methods following:

1. Sterilized filtered cultures of bacilli.

2. Strong cultures of killed bacilli.

3. Attenuated and repeated culture and transplantation.

4. Exposure of germs to drying in the air (Pasteur's first inoculations against chicken cholera).

5. Growing bacilli in some more or less devitalizing medium—as the solution of the thymus of the calf, or chemical agents such as sodium hyposulphite and alcohol (Sternberg).

6. Exposure to compressed air (Chauveau) or sunlight (Arloing).

7. By heat (anthrax bacilli).

8. Cultivation in non-susceptible animals—as tetanus and diphtheria in the horse (v. Behring and others), anthrax in the frog or rat.

9. Successive inoculations with dried infectious material of increasing strength (Pasteur's antirabic inoculations with dried infected spinal cords.)

10. By successive inoculations with small but gradually increasing doses of toxins—as in tetanus (Tizzoni and Cantani).

11. By single or multiple antitoxin inoculations (diphtheria, tetanus, Marmorek's antistreptococcus serum).

On the other hand, immunity, either natural, acquired, or artificial, may be lessened in a variety of ways. Thus it has been shown that either uric acid or sugar, present in excess in the blood, lessens resisting power against infection. White mice fed on phloridzin acquire an artificial diabetes, and when in that condition Leo succeeded in inoculating previously immune animals with glanders.

v. Behring has shown that white rats, ordinarily immune like other carnivores to anthrax, become susceptible upon a vegetable diet or a diet rich in phosphate of calcium. Arloing proved that a variety of chemical substances, inimical to the germs themselves, if inoculated with them, lessen immunity by weakening the tissues of the host.

Roger has demonstrated experimentally that in some cases inoculation with one infection favors susceptibility to inoculation with another to which the subject was previously immune. He also demonstrated with Aberrin that exhaustion and bruises greatly increase the susceptibility in guinea-pigs to the anthrax bacillus. Pasteur and Wagner, by refrigerating fowls and thus lowering their vitality, were enabled to counteract their natural immunity to anthrax. The same occurs in sheep after extensive venesection.

In summary it may be said that all the artificial immunizing agents fall under one or other of two classes: (1) They may be of the nature of a ferment, stored like an enzyme in the body of the leucocyte or that of the germ, or developed free in a culture medium. In this condition they may be supposed to act upon the blood serum almost indefinitely after inoculation, and like the digestive ferments, pepsin, trypsin, etc., being themselves not destroyed at once, but serving as agents for the manufacture of antitoxins out of the serum. (2) They may be finished products, true antitoxins, incapable of self-propagation and therefore incapable of maintaining indefinite immunity after inoculation, as far as their own substance is concerned. If, therefore, it can be shown that they do produce lasting immunity after inoculation, it must be through stimulation of leucocytes or of the body cells and tissues to greater resisting power. The latter explanation would transfer the ultimate cause of such immunity from the blood itself to the tissues.

There can be no question of the ability of the general body tissues, other than the blood, to acquire increasing and permanent toleration to external irritation of many kinds. In fact, this property constitutes one of the fundamental factors of evolution and of the

[1] Freyer: British Med. Jour., August 7, 1897, p. 329.
[2] *Loc. cit.*, p. 3.
[3] Lancet, August 28, 1897, p. 539.

adaptation of different races of man to environment. As familiar examples may be mentioned the acquired but permanent resistance of the skin to external applications of heat, cold, friction, pressure, etc.; the tolerance of the digestive organs in many savage tribes to food which, from its coarseness, monotony, or even commencing decomposition, would be promptly resented by more delicate organisms; the tolerance of the respiratory and circulatory systems to exceptionally high altitudes, as well as to the lack of oxygen in cases of extreme anæmia, and of loss of respiratory surface in advanced chronic tuberculosis. There is some analogy between the toleration of the tissues for drugs and poisons and for certain toxins. In both cases the young are usually most susceptible to the poison, and in both cases in adults increasing doses favor toleration. Yet such examples as the tolerance for opium in diabetes, for potassium iodide in syphilis, for alcohol in septic conditions, are not attributable either to the leucocytes or to the blood serum.

Among the factors concerned in lessening immunity to infection are many which are generally spoken of as "lowering vitality," and which are clinically described as "predisposing causes." Certain infections, like cholera and the bubonic plague, are well known to follow famine. Malnutrition, want of exercise, lack of fresh air and sunlight, alcoholism, prolonged exposure to cold and wet, the inhalation of dust and irritants, recent attacks of other infectious diseases, chronic maladies of different kinds, are among the many agencies which reduce vitality and lessen the resistance to the bacilli of tuberculosis, pneumonia, and other infections. Yet in none of these conditions is it customary to call the leucocytes to account, nor yet the blood serum, but rather the general tissues of the body. Cheyne has well shown how the alimentary canal during life may harbor without detriment enough saprophytic bacteria to decompose promptly the entire body as soon as death ensues and tissue resistance ceases.

Among the whole list of acute infections it is difficult to name one in which a second attack may not occur, however rare such examples may be; and between such extremes as measles and recurring erysipelas every grade of persistence of immunity is to be found.

The symptoms of any infection are finally manifested in the general tissues, in the nervous system, the mucous membranes, the serous membranes, etc., and to these tissues, from their greater variety and relative permanence in structure, must belong the major share of resistance to infection and of permanence in immunity.

From the foregoing arguments the following conclusions may be formulated:

1. The phagocytic action of the leucocytes in combating infection is of but little importance, and is mainly concerned in the removal of waste products rather than the devouring of living bacteria.

2. The leucocytes probably secrete substances which are both inimical to living bacteria and antagonistic to their toxins. The antagonism may be through digestion of the toxins and through counteracting the irritant effect of the toxins upon the general tissues and cells of the body.

3. The antitoxins of the serum, whether artificially injected or developed within the body, do not act by chemical neutralization of the toxins, but through stimulation to greater resistance of either the leucocytes or the tissues, or both.

4. The blood itself, neither through its leucocytes nor through its serum, is capable of producing all the phenomena of permanent immunity. To a limited extent only can it be relied upon for the prohibition of toxic symptoms.

5. It remains for the tissues to offer the final combat against the toxins, and to develop a more or less permanent resistance to them, which is transmitted to successive cell generations as more or less permanent immunity. To this effort they may be incited by either toxins or antitoxins, in addition to the exercise of the inherent property of living protoplasm to resent irritation of any sort.

6. It is probable that natural immunity does not differ in kind from acquired immunity, and that it is really originally acquired immunity which has been perpetuated for an unusually long period through succeeding generations.

VAGINAL CŒLIOTOMY—CONSIDERED AS AN APPROACH FOR THE REMOVAL OF MULTIPLE UTERINE MYOMATA.[1]

By A. V. WENDEL, M.D.,
AND
W. O. BAILEY, M.D.,
NEWARK, N. J.,
SURGEONS TO THE ALEXIAN HOSPITAL.

The removal of an organ not irreparably diseased, because at first no physiological reason can be adduced for its retention, is not good surgery. Experience has now convinced the profession of the necessity of retaining every portion of the economy not inimical to life and comfort. This postulate should be constantly before the surgeon's mind, encouraging him to develop a faculty of quick perception and faultless decision on the field, to meet exigencies as they arise. It is now an accepted rule that the uterus should not be extirpated without grave cause, but the lines are not always drawn distinctly, and the operator is often perplexed whether to sacrifice this organ, leaving his patient mutilated, perhaps destroying her mental and conjugal happiness; or to preserve it, risking the danger or at least annoyance of another operation, with the probable imputation of bungling work.

The removal by vaginal section of solitary myomata has become a recognized operative procedure, but until recently the uterus subject to multiple tumors was doomed to ablation. For several years we have made it a rule to attempt a conservative operation upon every case of multiple uterine fibroids, excepting those associated with an organ entirely disorganized, and this paper will be limited in its scope to a study of fourteen cases, which we have operated upon with conservation of the uterus, and the deductions therefrom.

Multiple myomata may remain stationary in growth, but in our experience they rarely do so. Whatever the etiology of myomata may be, the fact of multiple tumors has impressed us that the causative factor is more acute and the development of the individual growths more rapid.

If any one will take two series of cases, one of the solitary and the other of multiple tumors, and observe them carefully for several years as to their growth, he will become convinced of the truth of this statement. Even several mural tumors of small size cause distinct and annoying symptoms, which we believe to be caused by the mechanical irritation of the muscular substance of the uterus and the vascular excitement incident to their growth, which results in the enlargement of the organ. The nearer they approach the cavity of the uterus, the more accentuated the symptoms. Therefore we find these patients giving the history of dragging pains; excessive, painful, and irregular menstruation, alternating with leucorrhœal discharges: re-

[1] Read before the New Jersey Surgical Society, September 7, 1897.

flex phenomena, and later pressure symptoms with physical deterioration. It will probably be said that this picture is rather darkly drawn, but then we ask: Why do some authorities regard uterine myomata as almost malignant, while again others look upon them as of no importance, condemning operation as an unnecessary intervention? We believe that the solution lies in the very problem already stated: that solitary myo-

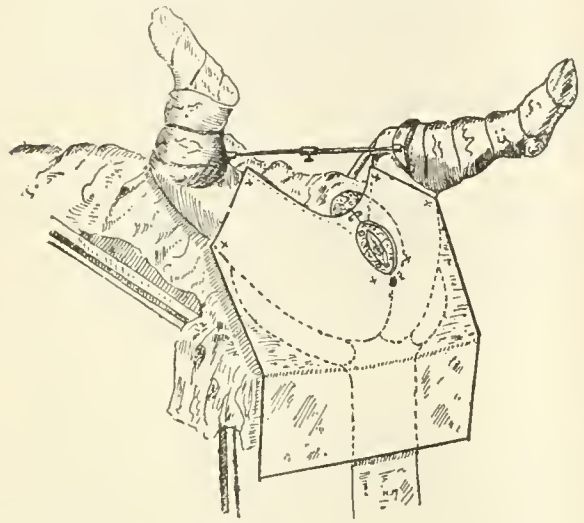

Fig. 1.

mata are generally of slow growth and more benignant, while multiple tumors are of more rapid growth and not so innocent.

It is well known that fatty or brown degeneration of the heart muscle is almost always present in patients who have large myomata within the pelvic cavity, even when hemorrhage is not a prominent phenomenon. One of the writers once heard an eminent and successful operator declare that he had never had a recovery in a case in which a fibroid weighed over fifteen pounds.

Sterility generally accompanies multiple fibroids, chiefly on account of the severe metritis, and, when pregnancy occurred in our cases, we have found abortion to be the rule. One of the women operated upon carried to term, but dystocia gave considerable trouble. Advising young women with multiple tumors to wait for the menopause is, for the reasons already mentioned, pernicious advice, because the menopause is always delayed, often many years beyond the usual limit. As to electrical treatment of multiple myomata, one of the writers gave each of our patients a careful trial of this method, without any other result than ameliorating somewhat the endometritis in three of them.

While we hesitate to advise operation when the development requires ventral section, we do advise the early conservative removal of even very small multiple tumors in every case, when observation of several months shows any growth, particularly if any tendency to extend into the ligaments is manifested, because the sooner it is attempted, the easier the operation and the better the result.

Coincident suppurative endometritis leads us to select hysterectomy, and bilateral suppurative disease of the appendages calls for total extirpation. The most difficult question to answer is: What constitutes the limit of size of fibroid tumors which can be removed by conservative vaginal section? Much depends on the localization of the growths, the experience and skill of the operator. Every case should be carefully examined under full anæsthesia several days before operation, because the operator will have more time to reflect upon and mature his plan of operation; frequently will he find cases very appropriate for vaginal section when he has decided for hysterectomy, and often again the reverse. In all patients with marked development we demand consent to extirpate the uterus in case we should find it necessary.

Technique.—The preparatory treatment is the same as for hysterectomy. The patient is anæsthetized and placed upon the table in the lithotomy position. A most annoying spot to the operator is the anus; no matter how thoroughly the field has been cleaned, frequently some flatus escapes, bringing down a little mucus, which may very readily infect a pendent instrument, or the hand; therefore we take a good-sized piece of sterilized rubber dam, with an aperture corresponding to the size of the vulvar commissure, and stitch it to the fourchette and thighs, as shown in Fig. 1. The perineum can then be pushed up or back, or an assistant may insert his finger into the rectum, without the least danger of infecting the field. A Simon or Fritsch speculum retracts the perineum; the uterus is thoroughly curetted and washed out, but not packed, because the uterine cavity may be opened. The gauze would then interfere with suturing the wall.

Erosions are burned with the Paquelin cautery. The vagina is thoroughly flushed out with sterilized water and swabbed dry. Two lateral retractors are inserted, widely separating the labia. An incision is made anterior or posterior to the uterus, or both incisions may be required, according to the location of the tumors. Unless the tumors be limited to the anterior aspect of the uterus, it is advisable first to incise the fornix in the post-cervical crescentic fold, open Douglas' pouch, and explore. If the anterior fornix requires opening, we employ the sagitto-coronal incision, as shown in Fig. 2.

With reasonable care the ureters are in no danger of being injured, and the amount of space gained compensates amply for the additional time and trouble. A bloody field protracts the operation; therefore bleeding points should be tied with fine catgut, as soon as they are severed.

The peritoneal apertures should be close to the uterus, and extended well on to the broad ligaments;

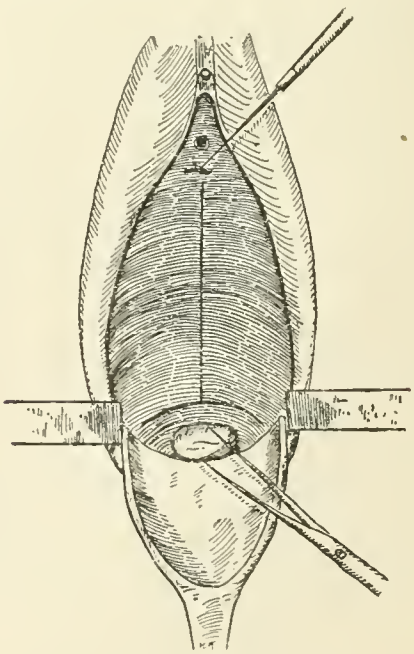

Fig. 2.

a vesical retractor keeps the bladder out of harm's way. Every portion of the uterus is now accessible.

A plentiful supply must be at hand of fine volsella; long, sharp-pointed and blunt-pointed tenotomes; delicate clamps with long handles; large and small Hagedorn needles, each threaded with a twelve-inch strand of medium fine chromicized catgut; curved and straight

iris scissors with long handles; together with several patterns of serviceable needle-holders. Two rectangular retractors with long narrow blades are often found useful, in order to expose satisfactorily the uterine surface during enucleation or suturing.

A stout volsellum is attached to the cervix and given to the first assistant. His function is to hold the uterus and nothing else. If there be intraligamentary development, a provisional ligature is placed upon the corresponding uterine artery. A Hegar uterine dilator is introduced into the uterus and the organ carefully palpated between the finger and the dilator, to determine the number and location of all the myomata. An incision is then made over the most prominent tumor and the capsule stripped back; if larger than a hazelnut, the tumor is grasped with a small volsellum and morcellated; if not, it is simply twisted from its attachments, and the bed is sutured with interrupted buried sutures, drawn tight. When there are other growths juxtaposed to the one removed, the bed is not sutured until the entire nest is extirpated. Blunt dissection must be employed wherever possible.

Whenever the uterine cavity is opened, the sutures shall be so placed that when the sides of the wound are apposed the strands are not exposed to infection. The uterus is sometimes decidedly mutilated after a conglomerate mass has been removed, and at times some ingenuity is required to close the crater. Spaces left in the parametrium should be drained with gauze strips brought out into the vagina. When a case is complicated with adhesions, they are carefully separated; any other morbid process must receive appropriate treatment.

The wound or wounds are then swabbed dry, sutured, or left open, according to the requirements of the case. The vagina is packed with sterilized gauze, which is changed every second day. Catheterization and the dietary usual to cœliotomies are prescribed. If everything does well, the patient is allowed to sit up on the eighteenth day. It looks very well to have the patient up sooner; but there is no good reason why after a cœliotomy the result should be jeopardized by allowing the patient to get up at an earlier date than we would if the same patient had had simply a plastic operation performed.

Prognosis.—The operations were all tedious, but the patients left the table with very little, often no shock; none died. All except one convalesced without unusual incident. There are no unsightly scars, neither will there be ventral hernias to worry about. We believe that these facts appeal in favor of vaginal cœliotomy in every case when the development is not too great to preclude extirpation by the anterior or posterior incisions of the fornix, or when the uterus is not so disorganized as to require extirpation. In one of our series of fourteen cases we found a small tumor in the posterior wall of the corpus, two years post operationem; the other thirteen have not shown anything suspicious up to the present time.

The most distorted uteri have regained a fair degree of symmetry. Pregnancy has occurred twice. Case III. was delivered at term in July of the present year, and Case IV. aborted by criminal induction at the second month of gestation.

Report of Cases.—Case I.—R. N——, widow; one pregnancy sixteen years before; complains of severe backache and menorrhagia. She is much debilitated. She began menstruating at fifteen years of age, her periods never lasting more than three days until five years ago; the flow has gradually become very profuse. The duration is now nine days. She has also occasional floodings between the menstrual periods. Digital examination determines a mobile, large, painful uterus, with a hard, irregular bulging of the corpus, and filling the lower portion of the Douglas pouch. A sound can be introduced four and a half inches.

Four months of electrical treatment by the Apostoli method, without benefit. Operation, November 21, 1895.

Posterior vaginal section; enucleation; mass is found to be composed of four myomata, one as large as a hen's egg, and the three others about the size of walnuts. Cavum uteri opened to about one centimetre. Wound closed with nine interrupted catgut sutures.

Drainage of the Douglas pouch. Convalescence uneventful.

Examined on December 28, 1895. Uterus mobile; cavity four inches deep.

Examined on April 3, 1897. Uterus normal, no development of tumors, menses regular and four days in duration, no backache, no dysmenorrhœa.

Case II.—M. H——, aged thirty-eight years, IV.-para. Menstruation began at sixteen years of age; lately more profuse. She married at the age of eighteen. Last child eleven years old. She noticed three years ago that defecation became painful; is now getting worse, and desires relief. Bimanual examination shows a pedunculated subserous fibroid growing from the left cornu and a mural tumor in the posterior wall of the corpus, about the size of an orange.

Operation, December 5, 1895. Sagittal incision of posterior wall after preliminary vaginal section. Fibroid enucleated, cavity opened; eight sutures. The subserous tumor was then pushed down, grasped with colpotomy forceps, the pedicle ligated, and the fibroid cut away. A strip of gauze was left in the Douglas pouch for drainage.

Examined April 5, 1897. Uterus slightly enlarged, otherwise normal. No rectal difficulty.

Case III.—B. S——, aged thirty years; married eight years; sterile. Applied for relief for severe dysmenorrhœa of nine years' standing, also for seven months of continuous stillicidium bleeding. Bimanual examination discovered a distorted and enlarged uterus, the organ being studded with elevations on its fundus, anterior and posterior walls. The uterus was curetted, iodined, and then submitted to electrical treatment for six months. For several months some improvement occurred, but by the sixth month it became evident that something more had to be done.

Operation, December 22, 1895. Anterior and posterior vaginal section. Eleven tumors, varying from a pea to a walnut in size, enucleated, the uterine cavity being opened in two places. The wounds were sutured and the Douglas pouch was drained.

Convalescence uneventful.

On June 19, 1897, the patient was delivered at term. The fœtus weighed four thousand and sixty-one grams.

Case IV.—M. J——, aged twenty-nine years; once pregnant, seven years ago. Gives a history of metrorrhagia, menorrhagia, discharges, and dyspareunia during the past four years. Physical investigation reveals a uterus somewhat large and fixed, a painful mass to its left and rear intimately incorporated with it and adherent to the surrounding structures. Also on the anterior wall of the body a lump the size of a walnut.

Operation, January 5, 1896. Posterior vaginal section. After thorough separation of adhesions, the mass was found to consist of prolapsed adherent ovary and hæmato-salpinx. A myoma as large as a hen's egg was growing from the left side of the uterine body and projecting into the ligament. The anterior fornix was next opened, and the left uterine artery ligated; the tumor on the anterior wall was removed and its bed sutured. With a full-curved Dechamp a ligature was passed around the ovarian artery and tied. The cervix was then pulled forward again, the tumor removed by

morcellation, its bed being partially closed by suture. Lastly the appendage was delivered into the anterior incision and extirpated. Drainage by the Douglas.

Examined on February 16, 1896. Uterus slightly drawn to the left, a little large but painless. Eleven months after operation she conceived: submitted to criminal abortion at the second month, which culminated in septic endometritis and salpingitis with pelvic peritonitis. One of the writers was then consulted. The uterus was at once curetted, and the cul-de-sac opened up and drained. April 9, 1897, the patient was examined and found in good condition.

Case V.—K. L——, aged thirty-five years, single. Complains of menorrhagia and pelvic pains. Physical examination: Subserous sessile fibroid the size of an egg, involving fundus and upper portion of anterior wall of corpus; several smaller ones in posterior wall, also a cervical polyp.

Operation, January 21, 1896. The polyp removed by torsion; anterior and posterior vaginal section. Large tumor morcellated, bed closed by sutures passed from side to side. Four small growths removed from posterior wall. Drainage by Douglas.

Examined June 10, 1897. Uterus normal.

Case VI.—L. S——, aged forty-one years; dipara; last child fourteen years old. Subjective history of menorrhagia and dysuria. Objective symptoms: uniformly enlarged uterus: lump, size of filbert, growing from corpus near right cornu. The sound indicates a cavity four and three-fourths inches in depth, with a sessile protrusion from the posterior wall.

Operation, January 30, 1896. Posterior vaginal section. Sectio Cæsarea posterior nonparturientis, and the removal by morcellation of a soft myoma larger than a goose egg; then removal of the small subserous tumor by a separate incision. Suture and drainage.

Examined November 7, 1896. Catarrhal endometritis.

Case VII.—B. R——, aged thirty-eight years, tripara; last child would be twelve years old. History: Has had salpingo-oöphorectomy on the left side performed nine years before in one of our local hospitals, followed by a fistulous opening in the lower angle of the wound. The same closed two years later. She felt quite well for several years; then the "old pains" returned, and are now very severe. Physical examination: Uterus fixed, enlarged, bulging irregularly on the left side of the fundal and corpal divisions into the pelvic space and ligament. Sound detects a smooth sessile encroachment on the cavity from left cornual region of the uterus.

Operation, February 4, 1896. Anterior and posterior vaginal section. The extensively adherent omentum loosened. Incision over the uterine swelling; two juxtaposed tumors, each about the size of a butternut, removed. Opening into the uterine cavity, two centimetres in extent. Wound closed; drainage by anterior and posterior vaginal incisions.

Examined September 13, 1897. Uterus mobile: slight sinistro-flexion: no pains.

Case VIII.—L. D——, aged thirty-nine years, primipara. Obstinate severe menorrhagia and pain in left iliac region, aggravated during defecation and menstruation. Bimanually the fundus and anterior wall appear nodulated: a painful movable mass behind the broad ligament.

Operation, February 19, 1896. Anterior vaginal section. Three tumors about the size of a hazelnut removed from the fundus, a very small one enucleated from the anterior surface of the corpus, followed by suture. The ovary was microcystic, the tube distended with clear fluid; they were removed. Closure of vagina without drainage.

Examined September 6, 1897. Uterus and surroundings in good condition.

Case IX.—G——, aged thirty-one years, IVpara. "Desires relief for too frequently recurring and profuse menstruation of three years' duration." Examination reveals a small pediculated subserous fibroid springing from the fundus. Another tumor, as large as a butternut, was growing in the right side of the uterus, near the cervix, and invading the broad ligament. Four months of galvanic treatment without material benefit.

Operation, March 24, 1896. Anterior and posterior vaginal section. Right uterine artery ligated. Morcellation and removal of a telangiectatic myoma; operation tedious on account of hemorrhage. Troublesome oozing continued after removal of the tumor, which subsided after ligature of the ovarian artery. Finally, removal of the subserous fibroid. Tamponade of the irregular cavity in the broad ligament from the anterior incision; gauze removed on the second day after operation.

Examined August 21, 1897. Uterus subjectively and objectively in very satisfactory condition.

Case X.—M. G——, aged forty-two years. "Has never been well since the delivery of her only child, twenty-three years ago. Metroperitonitis and phlebitis supervened on the seventh day *après l'accouchement*, leaving her in delicate health and sterile ever since. But she notices that for two years her pains have steadily increased, and that menstruation is decidedly copious, which weakens her very much." Mrs. G—— presents a very anæmic appearance. On examination the uterus is found enlarged, fixed, retroflexed, and nodular.

Tonics, hydrastis, and electrization for six months. Considerable general, but no local improvement.

Operation, April 5, 1896. Anterior and posterior vaginal section. With much difficulty the uterus and appendages are freed. Four small tumors are enucleated from the posterior wall, two from the anterior wall, and one from the fundus. Both tubes occluded and distorted at their fimbriated ends, therefore resected. Lastly, cervico-corporal vaginal fixation and drainage of the Douglas.

Examined September 3, 1897. The patient has improved her weight from one hundred and nine to one hundred and thirty-one pounds. Uterus anteverted, slightly adherent, but not painful on digital elevation.

Case XI.—E. S——, aged thirty-one years; single. Severe dysmenorrhœa and menorrhagia during the past four years. Digital examination shows a mobile uterus with an irregular enlargement of the fundus: the sound indicates a sessile bulging of the fundus into the uterine cavity. Four months of galvanism did not inhibit their growth.

Operation, May 26, 1896. Anterior and posterior vaginal section; sagittal incision of fundus. Removal of six small closely related fibroids. Uterine cavity opened. Suture of the crater-like wound. A strip of gauze left in the posterior vaginal wound for drainage.

Examined September 30, 1897. Uterus normal in size, consistence, and mobility.

Case XII.—E. H——, aged forty-three years: has had three pregnancies. The first was carried to term; the following two aborted at the second month. Uterus enlarged and nodulated. Galvanization for six months without change in condition.

Operation, May 26, 1896. Anterior and posterior vaginal cœliotomy. Eight small tumors enucleated. The day after the operation the temperature rose to 101.5° F. Urinary examination showed albumin and casts. The patient was cupped and purged, bringing the temperature to the normal in three days. The albuminuria disappeared after a week.

Examination, November 4, 1897. Uterus normal.

Case XIII.—V. T——, aged thirty-seven years.

Married fourteen years, but sterile. Referred for operation because of a rebellious dysmenorrhœa and menorrhagia. Examination reveals an enlarged immobile uterus of irregular contour. The sound detects several sessile irregularities.

Operation, October 9, 1896. Anterior and posterior vaginal section. Adhesions of the omentum, intestines, and appendages loosened. Two small myomata removed from the surface of the anterior wall of the corpus, one about the size of a walnut from the middle of the posterior wall just below the cornu. The uterine cavity is opened in both instances. Suture of the wounds. The occluded fimbriæ are separated; the probe shows them otherwise healthy. The right ovary is microcystic, therefore resected. Douglasial drainage.

Examination, August 12, 1897. Uterus normal in position, function, mobility, and consistence.

Case XIV.—M. J——, aged forty-five years, dipara. She consulted one of the writers in April, 1891, for pelvic distress. At that time the uterus was found to contain a very small tumor on the anterior wall of the body near the cervix; another on the posterior wall, which was soft, and about as large as a lemon. Examination by the sound negative. The patient was seen from time to time; the consequent examinations showed that the growths were increasing slowly in size. On December 11, 1890, she summoned the physician for fever and great pelvic distress. By examination the tumor in the posterior wall was found as large as a man's fist, very sensitive and of stony hardness.

Immediate operation was advised and accepted. Anterior and posterior vaginal section. The tumor on the anterior wall was first removed, its bed sutured, and the vagina closed. The belly was closed with gauze above the posterior growth, the capsule incised, and a gangrenous mural fibroid enucleated. The uterine sutures were placed at half-inch intervals. The abdominal packing was removed. The Douglas pouch was drained with gauze. Recovery uneventful.

Examined September 5, 1897. Uterus and surroundings in good condition.

Remarks.—The comparison of this series of cases submitted to conservative operation with those which were submitted to mutilating procedures gives us much satisfaction. True it is that convalescence is not so rapid or so brilliant as after hysterectomy, and that local or mechanical treatment must often be patiently employed for months afterward. But it is also true that we do not see the patients tormented by doubts as to their sexual fitness, with melancholia and other psychoses. We do not wish to be understood, however, as claiming an absolute field for vaginal cœliotomy. Large tumors will always be removed by ventral section, for very obvious reasons.

The surgeon will be required to exercise careful judgment in selecting the case for vaginal section, and, as we said before, the indications widen with experience and improvement of operative dexterity. We are certain that time will give vaginal section a permanent place among the methods of operative procedure for uterine myomata, by reason of the undoubted lesser danger of peritoneal inflammation, because the principle of drainage can be applied without unpleasant sequelæ, and also because the main arteries can readily be ligated at any moment, if emergency requires it. Our experience is that women dislike having the abdomen incised, and it is much easier to persuade them to accept vaginal cœliotomy. In conclusion we desire to thank our registrar, Dr. Hugh F. Cook, for kindly compiling the report of cases.

The best way to silence a patient who talks too much is to put the thermometer in her mouth.

LOCOMOTOR ATAXIA IN ITS MODERN ASPECT.*

By F. W. LANGDON, M.D.,

CINCINNATI.

No disease of the nervous system illustrates more clearly the contrast between the old and the new in neurological medicine than that which forms the subject of the present paper.

In tracing the varied conceptions of its essential nature which have prevailed during the half-century of its existence as a clinical entity, one reviews in outline the evolution of our knowledge of neuro-anatomy, physiology, and pathology, which has culminated in the recognition of "the neuron"[1] as the anatomical, physiological, and pathological unit of the nervous system, and has within the last semidecade revolutionized our ideas of nervous processes and diseases in general.

The various names of the disease are suggestive of the varying ideas of its pathological basis. Todd[2] (1847), who is credited by Gowers[3] with being the actual discoverer of the disease, appears to have given it no name. His reference to it is hardly more than a statement of the probable connection between muscular inco-ordination without paralysis, and disease of the posterior columns of the cord. Romberg[4] (1815) under the name of tabes dorsalis described the disease, without clearly separating it from motor paralysis of the cord. Duchenne,[5] of Bologne, in 1857, under the term progressive locomotor ataxy, reported cases to the Medical Society of Paris, which were published in the following year. His classic description obtained such wide circulation through the lectures of Trousseau[6] as to give to the malady the name of "Duchenne's disease." Duchenne suggested (1858) that the disease was "necessarily dependent on some structural or functional lesion of the cerebellum,"[6] and noted further that no anatomical lesion in the encephalon and cord was appreciable to the naked eye. This would suggest that the autopsy was made in a case which had not yet reached the sclerotic stage of the disease, and is significant in the light of our present pathology. Axenfeld[7] (1863), who made a microscopical examination of one of the earlier cases, states: "On the whole all these alterations clearly point to atrophy of the nervous tissue." The name "posterior spinal sclerosis" we owe to Charcot," 1879–80, whose genius unravelled the then tangled skein of cord diseases and thus brought order out of chaos. He placed the affection on a firm basis as a member of the group of "system" diseases. That Charcot even at that day was not fully satisfied that the "inflammation" or sclerosis was the primary lesion is shown by the following passage from his "Lectures":[8] "Sclerosis or gray induration of the nerve centres corresponds, you have not forgotten, to one of the modes of primary chronic inflammation. One of its most salient features is the hyperplasia with fibrillary metamorphosis of the neuroglia, taking place at the expense of the nerve elements, or *proceeding at least on parallel lines with the destruction of those elements*" (italics by writer). Certain later writers,[21] recognizing the difficulty presented in attempting to account for a primary cicatricial process affecting only certain tracts of the cord, advanced the theory, based on microscopic sections, of a meningitis of the posterior roots, here again evidently mistaking an effect for a cause, the pathological anatomy for the pathology, a result for a process, the ashes for the fire!

In the "Rückenmarksschwindsucht"[9] of Mobius and modern German authors we have another designation with a pathological significance.

* Read before the Mississippi Valley Medical Association, Louisville, Ky., October 6, 1897.

Finally, if a name is needed to indicate our present-day knowledge of the pathology of the disease, it should be called sensory-neuron degeneration.

The literature of the subject is voluminous, comprising according to Möbius[9] some two thousand essays. Among these only a brief reference is permissible to some of the more recent publications which have made possible our present knowledge of the pathology of the disease.

The description by Waldeyer[1] of "the neuron" as the nervous unit (1891) was followed by the demonstration by Cajal[10] of the individuality of the neuron, thus disposing of the older conceptions of the central nervous system, which up to this time was considered

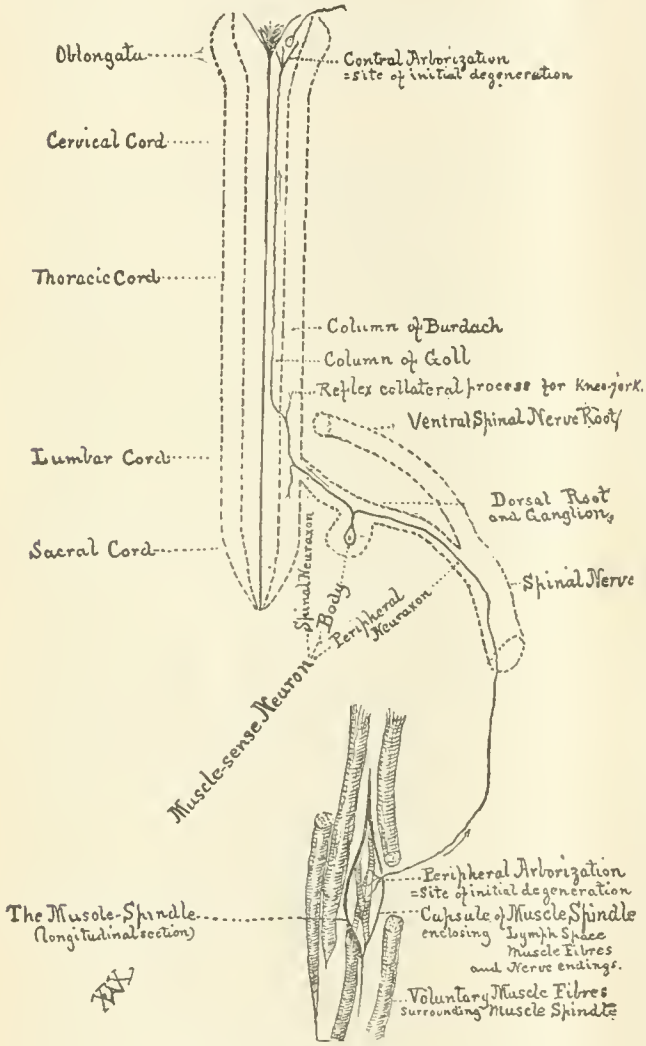

Fig. 1.—Scheme of Structures Involved in Lesions Causing Locomotor Ataxia.

to be a continuous network, or a homogeneous molecular mass pervaded by a network of fibres and fibrillæ.

Both the preceding were rendered possible by ingenious methods of staining (chrome-silver method) devised by Golgi.[11]

Summaries, in English, of the leading facts contained in these essays have been contributed by Schafer,[12] Andriezen,[13] Gowers,[14] Dercum,[15] and the writer.[16] Marinecso[17] has published (1896) a magnificent work on tabes, based on investigations carried out in the Charcot Laboratory at La Salpêtrière.

Last, and perhaps most important of all, with direct reference to the present subject, are recent papers by Sherrington[18] (1895) and by Batten[19] (1897) on the "muscle spindle" and its nerves, normal and pathological.

As is usually the case, a better anatomical and physiological knowledge has led to corresponding advances in the domains of pathology and treatment. The "scleroses," with which a former generation of students were mystified, have all, with perhaps a single exception,* been set in the background as primary pathological processes. In their place we have the "degenerations" of malnutritional, toxic, or hereditary origin; the "scleroses" being simply a result, not a cause, of the degenerations.

This is emphatically the case with the disease now under consideration, "posterior spinal sclerosis," as it was called in bygone days. We may all remember the vigor with which it was pictured to our imaginations up to a few years ago, a picture which even now holds a time-honored place in many of the current text-books—the exudation of plastic lymph, the round-celled infiltration of the neuroglia, the proliferation of connective-tissue elements, the organization of the cicatricial tissue, its contraction around the delicate nerve fibres, choking the very life out of the nervous tissue; the sad clinical picture of abolition of function after function, and finally the hopeless prognosis coupled with the despairing suggestion to give some iodide of potassium, because the patient had probably needed it in former years.

Fortunately for the unfortunate subject of this malady, this pessimistic pathology, therapy, and prognosis no longer apply in all their hopeless features.

With respect to the later pathology of locomotor ataxia, we find no less an authority than Möbius[9] saying that "tabes is parenchymatous atrophy, not syphilitic neoplastic growth;" and Marinesco,[17] working in the Charcot laboratory at Salpêtrière, says: "The type of direct parenchymatous degeneration of the sensory neuron, terminating in sclerosis, is tabes." The sclerosis, therefore, when it exists, is a sequel of preceding death of nerve fibres; there is even some reason to believe it may never occur, provided the diagnosis is made early and the nutritional aspects of the treatment are recognized.

It is just here that the newer pathology of the disease holds out hope to the tabetic. There is every reason to believe that, while the peripheral sensory neuron, as a whole, is lowered in its nutritional integrity, the actual destructive changes (parenchymatous degeneration) always begin at the endings (arborizations) of the axis cylinders (neuraxons), these being farthest removed from their trophic centres (the neuron-bodies in the spinal root ganglia). Hence the disease is primarily and simultaneously manifested at two places, namely: (1) in those arborizations conveying sensory impressions from the voluntary muscles; (2) in the terminal arborizations, in the oblongata, at the upper extremities of Goll's and Burdach's columns (see diagram, Fig. 1). The destructive changes may remain limited to these regions for a variable time, during which the typical symptoms of tabes are present.

In a preceding article[20] the writer has touched upon this aspect of the problem, and has taught it in his clinical lectures during the past three years.

To Dr., now Sir William Gowers his acknowledgments are due for first directing his attention to this conception of the pathology of tabes, among many other kindnesses received while a student in his wards at the National Hospital, Queen Square, London.

It will be seen at a glance that we have in this conception of the disease the explanation of those otherwise mysterious cases, with typical symptoms of tabes but no post-mortem findings of sclerosis in the cord. Had the oblongata and peripheral nerves been examined by appropriate methods in these cases, the lesions would doubtless have been apparent enough in those situations, not as sclerosis, but as degeneration.

* Disseminated sclerosis.

It may be said that the evidences for the peripheral beginning of tabes have been heretofore chiefly clinical and pathological. Recently, however, anatomical and experimental proof has been forthcoming in the work done by Sherrington[18] and by Batten[19] on the muscle spindle.

The muscle spindle (Figs. 1 and 2) may be described as an organ of sensation within an organ of motion. These bodies, whose existence has been known but generally misinterpreted for fifty years, have recently been proven by experimental and pathological evidence[19] to subserve a sensory function. They are probably the true organs of the muscular sense, including posture and weight senses.

They are spindle-shaped bodies with an outer laminated sheath or capsule, inclosing a lymph space in which lie a number (two to six) of small striated muscle fibres. In diameter these measure about one-third the average of the surrounding voluntary-muscle fibres. These spindle or "intrafusal" fibres are also peculiar in that they divide within the sheath into a number of parts, which, traversing the interior of the spindle longitudinally, finally reunite to re-form larger fibres and pass to its distal end; some are said to pass outside the sheath at either end. Throughout all this subdividing and reuniting they preserve their distinctiveness of structure so as to be easily recognizable from the ordinary voluntary-muscle fibres, from which they are separated, moreover, by the distinct laminated fusiform sheath or capsule of the muscle spindle.

It follows necessarily from this subdivision and reunion of the intrafusal fibres that the number of individual fibres or fibrillæ visible on a transverse section (Fig. 2) varies according to the situation of the section with reference to the poles of the spindle.

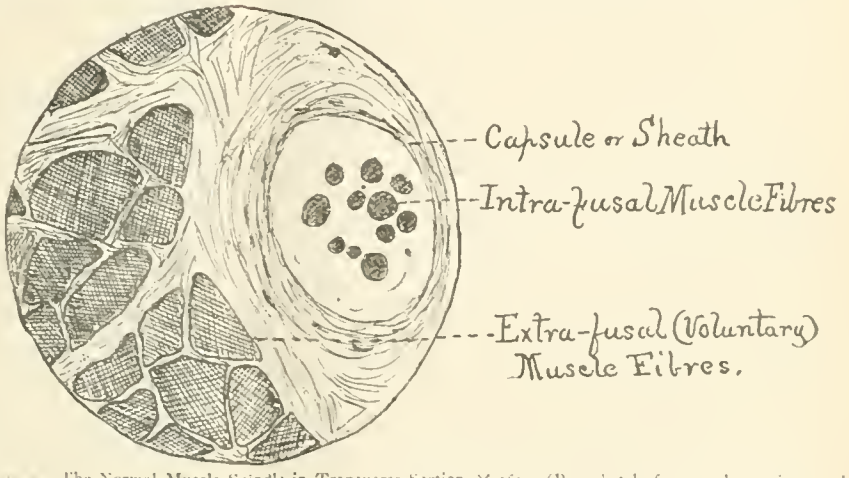

Fig. 2.—The Normal Muscle Spindle in Transverse Section, × 160. (Pen sketch from a photo-micrograph by Batten. *Brain*, 1897, p. 156.)

In addition to a distinct artery and vein, each spindle possesses a separate nerve supply; these nerves, moreover, are afferent in direction, having been proven by Sherrington to pass to the cord *via* the dorsal roots. Hence they are doubtless sensory in function. Such muscle spindles have been found in nearly all the muscles of the body, excepting the eye muscles, the intrinsic tongue muscles, and the diaphragm.

Batten, from whose very interesting and important paper[19] this summary is mainly taken, has demonstrated:

1. In tabes a degenerative change affecting the nerve endings and contiguous parts of the intrafusal muscle fibres. The nerve fibre itself (outside the muscle fibre) and the spindle in general were intact.

2. In poliomyelitis the muscle spindle and its nerve endings and nerves remained normal, while the voluntary muscle outside the spindle had undergone complete atrophy.

3. In myopathy and progressive muscular atrophy the muscle spindle and its contained nerves were likewise normal.

It is quite clear, therefore, that the pathology of locomotor ataxia bears a most intimate relation to lesions of the nerve endings within the muscle spindles; and, while it has been strongly suspected of late, on the basis of general neuro-pathology, that tabes is a peripheral disease in its primary manifestations, these investigations would seem to establish the fact beyond a reasonable doubt.

The evidence for the simultaneous degeneration at the upper end of the sensory neuron in the oblongata is less conclusive, resting mainly on the tendency of toxic degenerations to begin at the points farthest from the source of nutrition for the fibre, *i.e.*, the neuron body. In other words, when the whole neuron is impaired in its nutrition the extremities die first. This is well seen in the ordinary neuroses of toxic origin due to lead, alcohol, etc.

That the consecutive sclerosis is mainly limited in most cases to Goll's columns in the cervical and thoracic regions, and to Burdach's columns in the lumbar region, is readily explained by the course of the spinal neuraxons for the lower extremities, these passing down the cervical and thoracic cord in Goll's column and crossing in the lumbar cord to Burdach's column and posterior root zone (see diagram, Fig. 1). Since the degeneration probably proceeds downward in these fibres (toward the neuron body in the spinal ganglion), the sclerosis naturally follows the disappearing fibres down the thoracic cord and eventually appears in Burdach's columns in the lumbar cord.

In "high up" tabes and in advanced cases in which the arms are affected, the columns of Burdach in the cervical cord are likewise involved. The scattered points of degeneration in other tracts are due to involvement of collateral processes of the neuraxons (reflex collaterals). Thus variations in the severity and extent of the degenerative process give rise to the varieties of "pattern" of the diseased areas, as seen in transverse sections of the cord at various levels.

Viewed in the light of our present knowledge, therefore, locomotor ataxia is a periphero-central degeneration of sensory-neuron endings.

The pathology in its modern aspects, as it appears to the writer, may be briefly stated as follows: As a result of a predisposition, hereditary or acquired, and the action of a toxin or toxins (left by a preceding syphilis usually though not invariably), the nutrition of the nervous system as a whole is lowered. In certain groups of sensory neurons (muscle sense, iris reflex, optic nerve) the impairment is greater or the resistance of the tissue is less, and in these groups degenerative changes occur, beginning at the extreme ends of the processes (muscle spindles, oblongata, cervical cord). The muscle sense being biologically a late acquirement, the organs which subserve it are naturally less stable, less resistant to adverse influences than tactile or motor structures.

Other structures, not strictly sensory, are occasionally affected (ophthalmoplegia, ptosis, etc.), but it is notable that even these are in close functional connection with highly specialized sensory organs.

The tactile neurons also are eventually affected in a large proportion of cases. As suggested to me by my friend, Dr. Orpheus Evarts, the order of involvement

of the nervous functions bears a striking resemblance to that observed in ordinary senility; the more delicate and "special" sensory structures and co-ordinating mechanisms going first, the tactile and motor last.

Failing nutrition in the neuron bodies is first manifested by failure in function, later in structure, at the extreme terminals of their processes (fibres); hence the "lightning pains," lost knee jerk, ataxic gait, anæsthesias, etc., at one end of the tract; and the myosis, optic atrophy, ophthalmoplegias, ptosis, etc., at the other end—these being all evidences of primary degeneration of various neuron endings similar in all essential respects to that of an ordinary multiple neuritis, the main difference being that of function in the neurons affected. The visceral crises are also probably to be ascribed to similar nerve changes.

The initial destructive changes not only begin at the nerve endings, but may remain limited to them for a long time; hence the periods in which the disease is stationary, which render the term "progressive" locomotor ataxia a misnomer.

Sclerosis occurs as a comparatively late secondary process, filling in the spaces vacated by the degenerated fibres; hence the more limited the degeneration the less the sclerosis. Nothing can more forcibly emphasize the importance of nutritional treatment than this single fact.

The disease locomotor ataxia is to be carefully distinguished from the symptom locomotor ataxia due to other causes, as, for instance, that due to lead poisoning (saturnine tabes) and to syphilitic exudative lesions affecting the posterior columns or roots (pseudotabes). The distinction is not difficult, the history, course, and collateral symptoms being borne in mind, but is extremely important from the standpoint of treatment.

If our conception of the pathology of tabes has thus been revolutionized, this is no less true of its therapy. The mere fact that we have not primarily a sclerosis to deal with renders the indications for treatment more clear and the prognosis less gloomy. It is conceivable that early diagnosis and efficient treatment while the destructive changes are limited may bring about an arrest of the disease, and even a certain amount of restoration of lost function by (1) limiting the degenerative process to a small number of neurons; (2) by possible reproduction of certain nerve endings, as in ordinary multiple neuritis from alcohol, lead, etc.; (3) by promoting an increase of functional power in endings still competent, but lowered in vitality and function.

Möbius[9] says: "In so far as the peripheral nerve fibres are primarily affected in tabes, the tabetic symptoms are curable."

The prognosis of locomotor ataxia is not by any means so hopeless as is generally taught. Most cases not bedridden are susceptible of distinct improvement. In many cases this improvement is so great as to constitute a practical cure so far as the patient's comfort and general usefulness are concerned. The cases with bladder complications are the most difficult to benefit, but even these are rarely hopeless.

In a former paper[22] upon this subject the writer has inadvertently misquoted Möbius in referring to him as "pessimistic in prognosis" as regards tabes. A more careful reading renders correction and apology necessary, as the following passage from his article[9] shows: "In any case the physician does well not to express himself too pessimistically. The patient has a right to encouragement, and the physician may point out the fact that the disease may improve or remain stationary, and should bear in mind that this may occur occasionally when the prospect appears exceedingly gloomy."

The earlier the diagnosis the better the prospects for the patient; hence every case of so-called rheumatism, not distinctly articular, should be rigidly investigated for signs of beginning tabes.

In the modern treatment of tabes, the old idea of giving "alteratives," mercury and potassium iodide, for their (doubtful) absorbent effect on cicatricial tissue, is giving way to measures addressed to the nutrition of the neuron.

There being no syphilitic exudation in true tabes, antisyphilitic treatment is uncalled for. Diet, hygiene, rest, are the main factors in the successful management of the disease. Digestion, assimilation, elimination, must be promoted. Climate, medicines, and electro-therapy are of distinct value.

Distressing symptoms, the "lightning pains," "ataxia," etc., are to be alleviated without impairing the general nutrition. Opiates would better be avoided.

Rest in bed is a valuable measure when obtainable. The patient should sleep much and work little. When complete rest is not practicable, a few extra hours daily in the horizontal position is advisable.

The diet should be liberal—meats, fats, milk, water in abundance, and fruits, with a minimum allowance of starchy and saccharine foods. Alcohol is to be prohibited.

The patient should wear warm clothing, and if possible spend his winters in a warm climate. Measures addressed to the elimination of auto-toxins generally by the skin, kidneys, and bowels, should be instituted.

Drugs of more or less use in the treatment are those of nutritional value, mainly phosphorus, iron, cod-liver oil, with tonics such as strychnine.

For the lightning pains aluminium chloride (dose, two to four grains in water) is a drug of considerable value. Dr. Gowers originated its use for this purpose.

Electricity is of distinct value in a large proportion of cases. Ordinary faradism is useless, galvanism better. The writer's experience has led him to value highly that form of electricity known as the "sinusoidal" current.[17] It is a current of "high potential" (voltage), rapid alternation (480 to 1,920 per second), and comparatively small "quantity" (amperage). Its application is simple and controllable, as well as pleasant to the patient. It is administered by means of a "foot plate" and a neck electrode for from five to fifteen minutes every alternate day for six weeks. Under its use, with simple hygiene and often without drugs, the lightning pains cease, the ataxia of gait and station disappears, and the well being of the patient is promoted. These effects would seem to indicate an actual improvement in the nutrition of the peripheral sensory neuron, with capacity for better function in some, possibly restoration of damaged nerve endings in others. This six weeks' course of treatment may be repeated once or twice yearly as indicated, with advantage to the patient.

Patients treated by the foregoing methods have been under observation for nearly two years without relapse of pains or ataxia, and with full capacity for ordinary business affairs. All cases are improved, some more than others, depending on the stage and extent of the disease. Many additions to cases formerly cited[20] might be made, but space and time forbid.

In conclusion, it may be stated that, by reason of clearer conceptions of its pathology, leading to a more rational therapy, locomotor ataxia becomes a more hopeful disease to treat.

ANGINA PECTORIS.[1]

BY WILLIAM S. CONNERY, M.D.,

SAGINAW, MICH.,

PRESIDENT OF THE SAGINAW COUNTY MEDICAL SOCIETY; SURGEON TO SAGINAW HOSPITAL, WOMAN'S HOSPITAL, AND SAINT VINCENT'S ORPHANS' HOME.

While heart disease generally, of whatever kind, is remarkable for the almost entire freedom from pain—so that when patients come complaining of pain in the cardiac region it is a presumption against the existence of any serious organic affection of the heart rather than an indication of any such change—there is one form of pain in and around the heart, angina pectoris, which is very definite and constant in its significance of disease and of danger.

In a characteristic attack of angina there is intense pain in some part of the cardiac region—in the left breast or behind the sternum, or across the chest, at its upper part usually, but occasionally lower down, with radiation down the left arm. Accompanying the pain are a sense of utter powerlessness, and extreme fear and dread. The patient stands still, not daring to move or breathe, and feels as if he were in the act of dying. He will say afterward that if the pain had lasted another minute he must have died. In no other condition is the physical agony of dying realized in anything like the same degree. The two elements of pain and sense of dying coexist in a true paroxysm of angina, and are almost equally characteristic.

[1] Read before the Saginaw County Medical Society.

The pain differs in character and situation and in intensity in different cases. Some sufferers will say that it is indescribable; nothing in their previous experience suggests even a comparison. Others speak of the pain as a severe cramp in the heart, or as if the heart were gripped by an iron claw; while pain of a shooting neuralgic character, sometimes intermittent, sometimes persistent, seems to radiate from the chest to the left shoulder, the inner side of the arm, the forearm, and the third and fourth fingers. Occasionally there is a sensation as of the wrist being grasped so tightly as to cause pain. With the pain in the heart there may be pain down both arms or shooting up into the left side of the neck, very rarely in the right arm only. Occasionally the pain may be felt first in the arm and seem to travel up to the chest, or may come in the inner side of the arm as a kind of warning of an attack. Another description of the pain is that it feels as if the sternum were being crushed back to the spine, or, again, as if the whole chest were being held in a vice. In other cases the pain is compared to a bar of iron across the upper part of the chest; in others, again, to a ton weight upon the lower part of the chest. The ramifications of the cardiac plexus and its communications with other nerves make the radiation of pain in all the various directions enumerated comprehensible, and the nerve of Wrisberg has been specially instanced as explaining the pain in the left arm; but no explanation can be given why in one case the pain is felt in one part of the cardiac region, and has some particular character, and takes a given direction down one arm or both, or through to the back, while in another case the seat, character, and extension of the pain are quite different. It is not a pressure effect on the plexus outside the heart, neither heart nor aorta being necessarily enlarged, and extreme dilatation of the arch of the aorta being common without confirmed pain; and there can be no stretching or mechanical irritation of the ramifications beneath the endocardium at all comparable to that which takes place in acute dilatation of the heart. It seems probable then that the pain is really central, and that the radiation of irritation giving rise to its extension takes place in the spinal cord.

An interesting point is that at the end of a paroxysm there is usually flatulent eructation from the stomach. The attacks are therefore very commonly attributed to flatulence, and distention of the stomach by food or gases may undoubtedly be, and often actually is, an exciting cause; but more frequently the sensation as of wind on the stomach is only a part of the general commotion, and is due to communicated or sympathetic irritation of the gastric distribution of the vagus, the cardiac branches of which are primarily implicated. The escape of gas from the stomach is often a signal that the paroxysm is over rather than the means of bringing it to an end. Occasionally there is a great necessity to pass urine, although the bladder at the time may be empty.

The duration of the attacks is very varied: sometimes it can be reckoned in seconds. Most frequently, perhaps, a paroxysm will last a few minutes, but sometimes a patient will sit in the same position almost through an entire night, not venturing to make the slightest movement and scarcely seeming to breathe, while the perspiration rolls off his forehead and comes through his clothes. It is generally the attack that comes on in the night, without provocation by exertion or exposure, that is protracted. When it is started by exertion it generally ceases soon after the exertion is left off.

While it would not be justifiable to say that a patient was the subject of angina pectoris unless he had had one or more paroxysms of intense radiating pain, associated with a sense of immediately impending

death, it must be admitted that attacks of true angina occur which fall short of the typical development. For example, when a patient has been taught prudence by one or more bad attacks, he may, by standing still on the first warning, or by taking remedies, cut short the paroxysm, which will then have been represented only by the initial pain in the breast or arm without the mortal dread. It is possible, therefore, that before any characteristic attack has occurred, pains of a similar kind and intensity, disregarded by the patient or relieved by rubbing the chest or arm, may have the same significance as a fully developed paroxysm.

Again a patient who has had attacks of true angina may cease to suffer pain, but may have attacks of what he calls faintness, in one of which he ultimately dies. These, which have lost their title to the name angina, have an equally serious significance.

The aspect of the patient is one of extreme anxiety or alarm. He is usually pale and often livid round the mouth, but it is said that sometimes the color does not change. A cold perspiration usually bursts out on the forehead, and may be so copious as to drip off the face. The pulse is usually irregular, small, and weak. In some cases it has been reported to be very small from contraction or spasm of the arteries. In others, again, it has scarcely been affected at all.

Great importance attaches to the exciting cause of the paroxysms. In the first instance they are almost always brought on by exertion. The patient while walking perhaps faster than usual is more or less suddenly arrested by pain in the chest, with a feeling as if the heart were about to stop and he to fall down dead. When he stands still the pain gradually passes off, and he is able to resume his walk, but only feebly and gently. For a while the attacks occur only when provoked by exertion, but more and more easily as time goes on, and they tend to become more severe. They are more readily induced when a walk is taken, or any extra exertion, such as stooping, pulling open a drawer, pushing up a window, is made soon after a meal, especially after breakfast. External cold, again, predisposes to an attack, and exercise, which can be taken with impunity in mild weather, brings on a paroxysm if the air is cold and damp. Attacks can be brought on by indigestion or constipation, apparently either through reflex disturbance of the heart or as a result of pressure from the distended stomach or colon, carrying the diaphragm upward and obstructing mechanically the action of the heart and the expansion of the lungs.

They are also liable to occur during the night, and may be induced in various ways. The contact of cold sheets may have this effect by causing the contraction of the peripheral arterioles, and thus throwing increased work on the heart; or the upward pressure of the abdominal viscera, on assuming the horizontal position, may embarrass the heart. Not infrequently an attack comes on after sleep when the force of the circulation has run down.

It is clear that the great exciting cause is a demand for increased effort on the part of the heart to which it is not equal, or, what is equivalent to this, interference with the movement of the heart by a dilated stomach and colon.

The conditions of the heart associated with angina are varied, but perhaps the most remarkable and significant point in the relation between heart disease and angina is that angina does not attend the chain of events through which stenosis or incompetence of the mitral valve proves fatal, and is not among the symptoms which arise out of the valve lesion and its effects upon the heart. Instances have been recorded in which, after attacks of angina have occurred at intervals for many months, mitral regurgitation has supervened with dilatation of the left ventricle, and concurrently with the establishment of so-called mitral symptoms—pressure in the pulmonary circulation, dilatation of the right side of the heart, and dropsy—the angina has ceased. In these particular circumstances the giving way of the mitral valve may be an advantage to the sufferer from aortic disease.

Aortic stenosis may be attended by true angina, as may also, but less frequently, aortic incompetence and a combination of the two conditions of the aortic valve. In association with aortic valvular disease angina may be met with in early adult life, and may continue for many years without proving fatal. The sense of impending death is, however, not fully pronounced in many aortic cases.

Injury to the root of the aorta has been known to give rise to angina, as in injuries to the chest.

In aortitis there is usually angina; the attacks are at first slight, increasing in intensity and duration, and coming on more frequently as the disease advances. The heart rapidly becomes weaker without notable enlargement, the impulse is more feeble, the sounds are weak and short. Both the angina and the weakness of the heart point to interference with the coronary circulation, and post-mortems have found the orifices of the coronary arteries small and contracted by the swelling of the walls of the aorta.

Angina, again, has sometimes been an incident of diabetes, possibly from high arterial tension, which is commonly present in this disease late in life. Occasionally, however, a series of severe anginoid attacks, occurring at short intervals, has been followed by rapid failure and dropsy, suggesting that the angina was symptomatic of myocarditis.

In a very large proportion of the cases in which angina has proved fatal, the heart has been found, when examined after death, to be in a more or less advanced stage of fatty degeneration, and in most of these again there has been disease of the coronary arteries, very commonly so far advanced as to have reached the stage of ossification or calcification. Sometimes these vessels can be dissected out from the auricular grooves as rigid calcareous tubes. The fatty change in the walls of the heart may be so far advanced that the fingers sink into its substance on very slight pressure, and that scarcely a trace of muscular fibres can be found on microscopic examination. On the other hand, the degeneration may be comparatively slight, being evident to the naked eye only as yellow patches in the ventricular walls. The microscope, however, will show fat granules in those parts of the heart which to the eye and touch seem normal.

The condition of the heart during an attack has generally been supposed to be one of spasm, but there are great difficulties in accepting this view, and probably ideas as to what is meant by spasm of the heart in the anginal paroxysm by those who have employed the term have been diverse and very often vague. If by spasm of the heart is understood tonic contraction or an unrelaxing systole, this is certainly not the condition present. The heart has never been found in this state after death, and in most cases is absolutely incapable of such contraction from the state of its walls. No pulse would be possible were the heart in a spasm of this kind, and the pulse, though small and often irregular, can usually be felt. It has, indeed, in some cases been apparently unaffected by the paroxysm.

But by spasm may be meant an irregular and partial contraction like cramp in voluntary muscles, such as is induced by faradic currents in muscle. It has been suggested that the state of the heart in angina pectoris might be like hour-glass contraction of the uterus. Views of this kind cannot be proved to be wrong, but objections might be raised, and, for my part, I have to admit that I have no clear and definite idea of the state of the heart during the paroxysm.

The central fact and essential significance of angina is that stress is put upon the heart, to which, for the moment, it is unequal.

One of the main causes of such stress is persistent resistance in the peripheral circulation, or, in other words, habitual high arterial tension. In many attacks of angina there is an aggravation of habitual high tension by a general contraction of the arterioles. But the habitual state of the arterial circulation may possibly be one of relaxed arterioles and capillaries and low tension, so that the heart has no abnormal resistance to overcome. Here sudden general arterial spasm would put the heart to greater stress than if the habitual tension were high, since the contrast between the work demanded would be greater.

When the paroxysms of angina can be distinctly traced to arterio-capillary resistance, or when in the case of a patient subject to angina the usual condition of the circulation is one of high tension, the term "angina vasomotoria" may perhaps be appropriately employed. It is easy to imagine that stretching of the muscular fibres of the heart in the endeavor to overcome the resistance in the arteries might cause pain. But even when the vasomotor element is most potent, another factor must enter into the causation. Nothing is more common than high arterial tension, and it is met with in an extreme degree and produces fatal results without angina by ruining heart or arteries, or both, in hundreds of cases for one case in which angina is present. Acute dilatation of one or both ventricles again, in which stretching of the muscular fibres is obvious, frequently occurs without angina. The importance, and even dominance, of this second factor becomes clear when the cases of fatty degeneration are borne in mind, when the fibres must be incapable of producing anything like actual mechanical tension.

It has been assumed that the other element is neuralgic, and in a sense this is true, but not in the sense of a predisposing neurotic tendency. It must be remembered that angina is much more common in the male, which is the less neurotic sex.

Mechanical stretching and neuralgic predisposition being put out of the question, there remains the fact that the existence of the patient is threatened at the moment of the attack by arrest of the heart's action, and, were it not for the warning given by the pain and for the cessation of exertion enforced by it, the subject of the particular condition of the heart would die. We must, it seems to me, assume that angina is one of the defensive arrangements by which the adjustment of internal reactions to external conditions is secured.

The prognosis of angina is beset with uncertainty. We can never tell when the next attack will come on, or whether it may not be the last. While the attacks come on only when provoked by exertion or excitement, or by flatulent indigestion, the hope may be entertained that by care in avoiding all known occasions they may be postponed indefinitely. The patient, for example, must not take exercise immediately after eating, must never hurry or walk against a wind, and even on level ground must adapt his pace to his condition, and if compelled to go up hill must do so very gently and circumspectly. Angina in connection with aortic valvular disease may run a very protracted course. It is when the pulse is soft and the heart is normal in dimensions, with imperceptible impulse and weak sounds—when, in fact, the results of careful examination are negative—that the greatest uncertainty and danger exist. The occurrence of unprovoked attacks and of nocturnal angina will emphasize this conclusion.

The hygiene and general treatment of angina will be such as we use in the treatment of dilatation and degeneration, which, indeed, mostly underlie the angina, and the special precautions against the provocation of attacks have been indicated.

The great means of cutting short the attacks is that placed in our hands by Dr. Lauder Brunton, namely, nitrite of amyl or nitroglycerin; and a patient subject to angina should never be without one or the other of these remedies. The advantage of the former agent is the rapidity of its action. The best way is to employ the capsules, each of which contains from three to five minims of the drug. One of them is broken within the folds of a handkerchief, and the vapor is inhaled as freely as possible. In from fifteen to twenty seconds the face flushes, a sense of fulness in the head is experienced, the pulse at the wrist loses its tension, and the pain ceases.

Although the physiological action of nitroglycerin is less rapid than that of nitrite of amyl, it is yet commonly quick enough to cut short an attack if taken at the very commencement. But for this purpose it would better be given in solution, as pills or tablets, unless broken up by mastication, are too slow in their effects. The proportion most commonly used is an alcoholic solution of the strength of one per cent. The dose necessary to give relief varies very widely in different patients; sometimes several doses must be given in succession at short intervals before the pain can be entirely got rid of. In beginning the treatment it is generally best to prescribe one minim of the alcoholic solution and gradually increase the dose if necessary.

The great use of nitroglycerin, however, is in preventing the recurrence of seizures. In many cases if taken in one-minim doses three or four times a day, the patient is freed from his attacks, and may be able after a time to leave off taking it, and remain apparently well.

These two remedies are, no doubt, greatly abused, and many persons, feeling secure of obtaining relief, neglect the important precautions by which the real disease, of which angina is only a symptom, may be held in check; and so, if they escape suffering, hasten on a fatal termination.

Progress of Medical Science.

A New Symptom of Phrenic Neuralgia.—Dr. André Gousset (*Lyon Médicale*, August 29, 1897) says that a painful point, always present and well marked, exists in the median line of the sternum at the right of the fourth or fifth chondro-sternal articulation. This painful point should not be confounded with the diffuse retrospinal pain noted by Peter in chronic affections of the aorta. According to Dr. Gousset, these phrenalgias are frequent in the course of pulmonary tuberculosis in all its different stages.

Is Pleurisy of Tuberculous Origin?—That the above question would have been ridiculed a few years ago goes without saying. At the present day such results as are shown by Dr. George Sears (*Boston Medical and Surgical Journal*, August 5, 1897) in the use of tuberculin injections as a test are not only received with respectful attention, but such a publication as *The Lancet* (October 23, 1897), in commenting upon the subject, says that it would now seem to be proved that acute pleurisy is almost invariably of tuberculous nature. Mayor's conclusion "that the majority of cases of simple idiopathic pleurisy or pleurisy from exposure to cold conceal or reveal a tuberculous process," is quoted and is said to have been confirmed by Dr. Alfred G. Barrs, who read a paper on the subject at the Leeds Medico-Chirurgical Society in 1890. Reaction would seem to occur from the tuberculin injections in almost all instances, and point to tuberculous

processes in the future which should be guarded against by timely measures, hygiene, change of climate, and all measures of a prophylactic nature.

Bednar's Aphtha.—In an article devoted to this affection, which Dr. Alvarez, of Madrid, read at the Moscow congress, the following conclusions were drawn: 1. The aphtha of Bednar is of lymphatic nature: it is a primordial manifestation of scrofulism, or, more properly, of lymphatism. 2. The essential cause is the anatomo-physiologic condition of the epithelium and of the origin of the lymphatics of the mucous membrane, constant conditions of lymphatism. 3. Post-partum hyperæmia and epithelial exfoliation constitute a predisposing and local cause. 4. Repeated compression of the mucous membrane by the tongue and decubitus during the act of deglutition serve as occasional local causes, and influence the location and symmetry. 5. The lesion offers a port of entry which facilitates various infections. 6. The palatine vault should be constantly examined and watched in the newborn during the early weeks, since quite frequently these lesions exist without producing symptoms or apparent discomfort. 7. The aphthæ should be treated at once, and they cicatrize quickly under daily applications of nitrate-of-silver solution, 1 in 50. 8. Their scientific significance is that from the very beginning they call for treatment of the lymphatism.—*Abeille Médicale.*

Comparative Indications for Classic Cæsarean Section and Porro's Modification.—Carstens (*Journal of the American Medical Association*, December 4, 1897, p. 1,136) concludes a paper upon this subject with the following general rules: 1. Cases operated upon at private houses, with poor facilities and by inexperienced abdominal surgeons, should be subjected to the Porro operation, the extraperitoneal clamp method being used. 2. Cases of deformed pelvis, perhaps requiring a similar operation in the future, should be subject to the Porro operation, even if operated upon in a well-equipped hospital, unless the patient decides otherwise. 3. Cases requiring abdominal section on account of removal of tumors only should be subjected to classic Cæsarean section if the operation can be performed in a hospital, or in a private house where all proper facilities can be obtained. 4. Classic Cæsarean section should also be performed if the patient desires it, no matter what the future may bring forth.

Cystitis and Bacillus Coli Commune.—Thorkild Roveing ("Klinische und experimentelle Untersuchung über die infektiösen Krankheiten der Harn-Organe," Berlin, 1898) reports an interesting series of clinical histories of cystitis and allied disorders, as well as the results of some experiments on animals, and comes to the conclusion that the much maligned bacillus coli commune is not the cause of cystitis. This organism, although often present in infectious urinary diseases of all types, he considers an incidental growth, and not able to cause anything but the milder forms of bacteriuria, or in rare cases pyelitis or pyelo-nephritis. While he does not utterly deny the possibility of an unusually virulent form of bacillus coli producing cystitis, the author thinks that in the great majority of the cases of this disease the inflammation is the result of the presence of pyogenic urea, decomposing organisms, staphylococci, streptococci, proteus Hauser, coccobacillus septicus, etc. The author attributes the undue importance given to the bacillus coli by other writers to its extreme rapidity of proliferation, whereby its disproportionately greater numbers tend to mask the presence of the above slower growing forms, or to its power of checking the growth and actually exterminating certain pyogenic species, and lastly to the laxness with which any case of frequent and painful micturition with urine containing pus cells and bacteria is diagnosticated as cystitis. He insists that in every case, after the urethra is flushed, the urine which is to undergo bacteriological examination must be drawn direct from the bladder through a catheter, and that to differentiate cystitis from pyelitis or pyelo-nephritis it is absolutely essential to inspect the walls of the bladder through the cystoscope. Although the presence of the colon bacillus may sometimes be accounted for by direct infection through catheterization, the author thinks that the bacillus more often makes its way from its usual habitat through the blood to the pelvis of the kidney, less frequently to the vesical mucous membrane, and thence passes to the bladder.

The Specific Action of Quinine in Malaria.—Dr. E. C. Register writes in the *Charlotte Medical Journal* that malarial fever without complications will subside after the plasmodia of malaria disappear from the blood; that we have in quinine the means completely to eradicate malarial poison from the body; that malarial fever occurring in a previously healthy subject, and in the central United States, if at once recognized and properly treated, never ends in death; that it is speedily curable, never continues, provided the nature of the disease be recognized and appropriate treatment employed. He says that the crescentic and ring-shaped bodies are the forms of the parasite which are responsible for the continued types of this fever, and he finds that the reason quinine does not always affect these irregular forms of the poison is on account of defects in its administration. He contends that the drug is very imperfectly absorbed when given by the stomach, and when the patient has a temperature of over 102° F. In cases of continued malarial fever, if distinct and well-marked intermissions of the fever are produced artificially by the use of one of the synthetic antipyretics, the crescentic and ring-shaped bodies will disappear after the administration of quinine as quickly as the spherical bodies that are found in an ordinary case of intermittent fever. In reference to the belief that the forms of the parasite that inhabit the blood cells are not acted on by quinine, the writer thinks that most authors believe that the endoglobular or intracorpuscular forms are not on this account the cause of an uncontrollable fever, and that their proximity to the blood cell does not in any way protect them from the action of quinine.

Operation for the Prevention of Conception.—A woman who was still young had fallen into a state of grave anæmia after seven successive confinements, and Dr. Kehrer, professor of obstetrics and gynæcology at Heidelberg, performed the following operation, according to *La Semaine Médicale*, in order to prevent further pregnancies: By a median vaginal incision he penetrated the peritoneal cavity; then drawing the tubes into view he placed around them two catgut ligatures. This done, he performed vaginal hysteropexy immediately above the internal orifice of the uterus, introducing into the vesico-uterine cavity a strip of gauze and suturing the wound into the vagina so as to leave a small opening for the passage of the drainage. Apart from a little fever and slight suprapubic pain there were no sequelæ. This process of artificial sterilization possesses the advantages over castration of being a less serious operation, and of not bringing in its train the nervous troubles that double ovariotomy does. Dr. Kehrer thinks this could be done in certain grave affections (anæmia, pulmonary and cardiac lesions) which render pregnancy dangerous. He acknowledges that from a moral point of view the legitimacy of this operation could be questioned, and believes it ought not to be performed without the written consent of the parties concerned and a statement of the motives for such intervention.

MEDICAL RECORD:

THE PROGRESS OF MEDICAL EDUCATION IN THE UNITED STATES.

A RETROSPECTIVE survey of the progress made and of the reforms instituted in medical education in the United States is instructive. In many respects there is cause for much congratulation, while for other reasons the situation gives rise to feelings of alarm. It is pleasing to note and it augurs well for the future that a decided advance has been made in the direction of a more thorough medical training, yet at the same time it is discouraging to observe that, despite these progressive steps, competition does not abate, but rather daily becomes more acute. Dr. William T. Slayton has just issued his small annual volume on "Medical Education and Registration in the United States and Canada." From a study of this book, which fairly bristles with facts, a sufficiently comprehensive opinion may be formed in regard to the present state of medical education in this country. According to this work there is now a grand total of one hundred and fifty-four medical schools. Of this number one hundred and seventeen require attendance on four annual courses of lectures, and twenty-seven require attendance on sessions of eight months, and ten on nine months each year. Twenty-nine States and the District of Columbia require an examination for license to practise medicine; eighteen of these require both a diploma from a recognized college and an examination. Fifteen States require a diploma from a college recognized by them or an examination. Five States—viz., Vermont, Michigan, Kansas, Wyoming, and Nevada—have practically no laws governing the practice of medicine; Alaska the same. In order to gain a clear comprehension of the existing state of affairs, a comparison of the number of students at two periods, with a lapse of years intervening sufficient to eliminate all minor variations, will be more to the point than merely regarding the multiplication of schools. Many of these mushroom institutions are not worthy of notice, containing perhaps a dozen students, and brought into existence only for the purpose of profit or from other motives of self-interest. The number of students is as reliable an index as can be given. For instance, taking the decade between 1883–84 and 1893–94, it will be found that the students in regular schools in 1883–84 numbered 10,600; in 1893–94 they had increased to 17,601. Students in homœopathic schools in 1883–84 were 1,267; in 1893–94, 1,666. The number of eclectic students was stationary at the two periods. The increase during the period from 1893–94 to the present time has been at about the same ratio.

These figures reveal more plainly than words the existing condition of affairs, which must too in the nature of things continue until that time when all the States fall into line and resolve to adopt a four-years course of not less than eight months.

To make yet another comparison, the total number of medical schools in Austria and Germany, with a population exceeding that of this country, is twenty-nine. Great Britain, with more than half the population, has seventeen; while Russia, with one hundred million inhabitants, has nine. Of course we do not argue that America, with her immense territory and scattered population, does not need greater facilities for the study of medicine than do thickly inhabited countries, as Germany and Great Britain; but we do contend that when a city of the size of St. Louis has as many schools as Russia the craze for multiplying these schools is being carried to absurd and harmful lengths. However, that the number of schools and their yearly supply of graduates of medicine are far beyond the demand is perfectly well known to all. The MEDICAL RECORD and other medical journals have fully discussed and insisted upon that point for a considerable time. The real question at issue is by what means to remedy or at least to lessen the bad effects of the system as quickly as possible. The first and most important steps toward this desirable consummation have been already taken, and when a four-years course comes into practice throughout the country the difficult problem of checking excessive competition will at any rate be much nearer its solution. Why should France, Germany, Great Britain, and other European nations consider that a course of from five to seven years is not too long to acquire a good knowledge of medical work, while in many parts of America two or three years' training is esteemed ample for the manufacture of a full-fledged doctor? Such methods are unfair both to the public and to the medical profession, and the result is that in numerous instances the short-time graduate has either to learn most of the practical part of his duties by hard experience, to starve, or to utilize his abilities in some more lucrative path of life. Taking into consideration the fact that the theory and practice of medicine have become so extended within recent years, it must be readily conceded that four years is barely sufficient time in which to gain a satisfactory insight into their various departments. For a person, however gifted, to hope to receive an adequate medical training in two or three years is vain.

In those States in which the facilities for securing a medical education are abundant, and where the time and money to be expended are within the reach of every one, there is always the danger that an undue proportion will forsake trade in order to join the profession. This is especially the case when times are bad. Many persons seem to be possessed of the idea that the practice of medicine as a means of livelihood

should be regarded as a something to fall back upon when other resources fail. Accordingly when trade is depressed and money is scarce, there is a rush to enter its ranks. That this view of the matter is altogether an erroneous one is too self-evident to need any demonstrative proof. Again, although the question of a universal four-years course is a most important one, it must not be forgotten that examination takes almost as conspicuous a place. It is desirable that every one entering on medical studies should possess a general education. With the exception of a few unimportant schools, the entrance examinations would appear to afford the necessary test. Then comes the much more vital point of how to gauge in the fairest possible manner the extent of the medical knowledge of those who have undergone their full term of study. For various reasons the conducting of the final examinations by professors in the school in which the student has been taught is open to many and grave objections, more especially when these professors are themselves teachers in that school. As has been pointed out in the Medical Record on more than one occasion, the most obviously fair regulation is that of independent examination by an unbiassed State board. If this plan were carried into execution, medical education in America generally would rest on a firmer basis than in Great Britain, in which country the standard, although nowhere so low as in parts of the United States, still varies very considerably in the different schools. The General Medical Council of England has arrived at the conclusion that competition must be checked, and has lately brought into force two drastic measures calculated to attain this object; one is the lengthening of the course to five years, and more recently the abolishing of the unqualified assistant. The medical profession of America is quite as conscious of the disastrous results of competition as are its fellow-practitioners on the other side, and should use every legitimate means to sweep away the evils of the present system.

COLDS AND COUGHS.

The time of the year has arrived when colds prevail. In the changeable weather that ushers in winter, a chill is easily taken, and especially in the case of children. It is a moot point as to whether the fall or the spring is more productive of affections of the respiratory tract; perhaps the early spring is more to be dreaded on this account, but it is certain that in either season all reasonable precautions should be taken. Catarrh, the word used to express a cold in a general way, is derived from the Greek κατά ῥέω, signifying "to flow down," and this term accurately defines the unpleasant manifestations which are symptomatic of a cold. A well-known novelist humorously describes in the following words the condition of a person suffering from a cold in the head: "You are no longer human, nay, scarce animal; a thing laid on the shelf, a piece of useless lumber, or just redeemed the neuter gender by suffering." An ordinary cold in the head is too often regarded as so slight an ailment as hardly to be worthy of consideration, and its possible sequels are not considered in the serious light they should be. Because in a healthy subject a cold gets well, it does not follow that all colds will take that course, and everything should be done to prevent such attacks and to cut short probable complications. If a cold habitually flies to the chest, it may be taken for granted that there is an inherent weakness of the lungs, and the parents of children with such a predisposition should take steps to eradicate as far as possible the tendency; else the complaint may become chronic or tuberculous infection may result. Whether a common cold is contagious or not is a matter of opinion. Dr. S. Westray Battle thinks that the point is not clear, while Dr. Foxwell says that acute catarrhs are probably mutually contagious, and that pneumonia and coryza are generally recognized as being capable of reproducing themselves in fresh subjects. Dr. Moore, speaking at Dublin, says that "cold in the head is notoriously infectious, and the means of communication is the discharge from the nostrils;" and he is satisfied from repeated observation that this troublesome affection often spreads through a family of children and then through an entire household by the promiscuous use of the pocket handkerchief. That influenza is contagious is beyond a doubt, and whooping-cough also runs in epidemic form.

In regard to the treatment of colds, prevention rather than cure should be the motto. Bathing in cold water is often beneficial in preventing colds, or, to speak more accurately, in rendering the body sufficiently hardy to withstand the effects of a chill; but in this practice discretion must be observed. Children with delicate constitutions should be bathed in warm or lukewarm water, and this should be followed by energetic rubbing. Healthy exercise taken in moderation, as walking, riding, wheeling, or gymnastics, is a useful means of holding in check the tendency to catarrh. It is always advisable that children of marked catarrhal tendencies should wear woollen underclothing varying in thickness with the change of the seasons. A writer in a well-known journal gives as his opinion that a cold is frequently caught in bed. He discourses as follows: "I have a theory that most people catch cold at night after they are in bed, and it is to this fact I attribute a great deal of the violent colds, the bronchial catarrhs, and influenza which are so prevalent at certain seasons of the year. The temperature goes down suddenly in the night, and persons without knowing it catch cold when they are asleep. This evil is to be counteracted, not by piling on a lot of heavy blankets, but by wearing thick, close-fitting, woollen garments, and also warm socks on the feet."

There is much truth in these remarks. Cold is often caught in bed, particularly by children, who are frequently restless and kick off their bedclothes, and the consequence is that if clothed only in a cotton shirt a cold is the certain sequel. Woollen garments should be worn at night as well as in the daytime. The old saw to the effect that it is desirable to feed a cold contains the germs of common sense, and it is in many instances beneficial to eat heartily during the course of a cold, for the reason that the process of digestion, by increasing the capillary circulation throughout the

digestive tract, lessens the congestion of the mucous lining in other parts of the body. Finally, it can be laid down as an established fact that colds in most cases can be prevented by ordinary care and by adhering to the laws of hygiene.

News of the Week.

Randall's Island Hospitals.—Dr. Charles Warrenne Allen has been appointed consulting dermatologist to these institutions.

The New Health Board.—Mayor Van Wyck has appointed members of the health department: Mr. Nathan Straus, president and commissioner for two years; Dr. William T. Jenkins, commissioner for six years; Dr. John B. Cosby, commissioner for four years. The salary of the president is $7,500 per annum; that of each of the other commissioners is $6,000. Mr. Straus is known as the "milk philanthropist," because he was instrumental in causing the sale of sterilized milk in the parks in summer. He came in collision with the health board last summer, on the charge that the milk was below standard. The adulteration, if there was any, was evidently done without Mr. Straus' knowledge, and his prosecution savored of persecution. Dr. Jenkins was formerly health officer of the port, and caused great sorrow once to a well-known editor by keeping him in quarantine with the other unfortunate passengers on a cholera ship. Dr. Cosby is a practitioner of this city and a graduate of a Baltimore college in 1873. Dr. Robert A. Black, of Brooklyn, and Dr. George C. Hubbard, of Tottenville, have been appointed assistant sanitary superintendents for the boroughs of Brooklyn and Richmond, respectively.

The Bureau of Municipal Statistics. — Dr. John T. Nagle has been appointed by the mayor, chief of the bureau of vital statistics.

Department of Public Charities.—The following are the names of the new appointees to the department of public charities. It is to these that charitably disposed medical men, who burn to serve the poor as attending physicians and surgeons to the public hospitals, must turn for the opportunity to be philanthropic: John W. Keller, president and commissioner in boroughs of Manhattan and Bronx, for six years; Adolph Simis, Jr., commissioner in boroughs of Brooklyn and Queens, for four years; James Feeny, commissioner in borough of Richmond, for two years.

Obituary Notes.—Dr. Charles H. Jones, of Baltimore, died recently at the age of seventy years. He was graduated from the University of Maryland in 1851. He was the founder and first president of the Baltimore Medical Association.—Dr. Treffle Garceau, of Roxbury, Mass., died of heart disease on December 19th, at the age of sixty years. He was graduated in medicine in Montreal in 1863, and began practice in Lowell, whence he removed to Roxbury in 1869. He leaves three sons, one of whom is a physician.—Dr. John W. Hamilton died in Columbus, Ohio, on January 1st, aged seventy-two years. He was a graduate of the Willoughby University medical department in 1846. He was professor of surgery at the Columbus Medical College, and a member of many medical societies.—Dr. William E. Wentworth, of Mamaroneck, died on December 29th, of typhoid fever, at the age of twenty-four years.—Dr. Edward L. Dodge, of Brooklyn, died at his home, on January 3d, of pyæmia following an operation for carbuncle. He was thirty-eight years old, and was a graduate of the University Medical College in this city in 1886.—Dr. John R. Preston, one of the oldest physicians in Saratoga County, died on Sunday, at Schuylerville. He was born in Galway, Saratoga County, in 1809.—Dr. Franz Heuel, one of the oldest and best known German practitioners in the city, died at his residence, No. 320 East 21st Street, shortly after noon on Tuesday, January 4, 1898. Dr. Heuel was born in Prussia, Germany, on August 4, 1818. He was a graduate of the Berlin University. He took part in the German revolutionary movement in 1848, and as a consequence was forced to flee in this country in that year. He remained in New York ever since. After completing his studies at the Medical College of the City of New York in 1854, he went into private practice, and afterward distinguished himself by heroic conduct in the cholera epidemic in the '50's, when he treated many of the sufferers without pay and exposed himself to danger without hesitation. He was afterward for a time a medical inspector of the board of health, but relinquished the post many years ago. He leaves two sons, Dr. Franz Heuel and Dr. Emil Heuel, both practitioners in this city; also two daughters.

The First Born in the new New York was Edward Manhattan Van Wagner—a good, old Knickerbocker name. The first death was caused by diphtheria, in a ten-year boy named Bernecker.

The Minturn Hospital for Contagious Diseases.—This institution was opened for the reception of patients on January 1st. It is intended for the care of patients suffering from scarlet fever or diphtheria, who are of families in well-to-do circumstances, but who cannot well be treated at home and are not eligible for reception as charity patients in the public hospitals. The hospital is formed of a group of three buildings, which stand on a strip of land that juts out into the East River. The two pavilions—the one for the treatment of scarlet fever and the other for that of diphtheria cases—are L-shaped, two stories high, and built of red pressed brick. The third building, which contains the laundry and disinfecting-plant, is situated between the other two. On the first floor of the pavilions are the office, living-room, and laboratory of the physician-in-charge; the observation rooms, discharge rooms, solarium, kitchen, and dining-rooms, and twelve patients' rooms. The second floor is given over to the nurses', servants', and linen rooms, and on the roof is a small garden for use in summer time. A patient upon arrival is taken to the first of the observation rooms, where the diagnosis is made. If there be any doubt as to the character of his affection, he is

placed in a cot in the second room until the symptoms admit of a sure diagnosis. There are three rooms in the discharge section. In the first is an apparatus for disinfecting the clothing last worn by the patient. The second room is the bathroom, and in the third room the former patient puts on the clothes worn upon entrance, which have been thoroughly disinfected. Mrs. John W. Minturn gave the larger part of the money necessary for the construction of the hospital, and the city gave the land. The president of the board of governors is Dr. John W. Brannan; the secretary, Paul Tucker; and the treasurer, Louisa Minturn.

Dr. Joseph O'Dwyer, of intubation fame, is reported seriously ill at his home in Lexington Avenue.

Small-Pox in Atlanta.—During the past month it is reported that considerably over two hundred instances of variola have occurred in and about Atlanta, Ga. The cases have been found mostly in the negro quarters, and several schools have been closed in consequence.

Drug Clerks' Mistakes.—The recent occurrence in this city of several cases of fatal poisoning through error in compounding prescriptions has been made the occasion of a public appeal by the Druggists' League for shorter hours. The usual daily working-time of drug clerks is fourteen to sixteen hours, and the members of the league contend that the mistakes in substituting morphine for quinine, and the like, are attributable to exhaustion and blunting of the faculties consequent upon this long strain. A bill has been prepared for presentation in the State legislature this winter, restricting the druggists' work day to ten hours; and, in addition to pressing this bill, the league intends to call the attention of the January grand jury to the matter.

The Nobel Prizes.—The will of the late Alfred Nobel, who died a little over a year ago, has just been proved. He left about half of the estate to relatives, and the remainder is to be invested, the interest being divided into five prizes of about $10,000 each. Three of these prizes are to be awarded to the persons making the most important discoveries during the year preceding in physics, chemistry, and physiology or medicine. Another prize is to be given to the person making the best literary contribution upon the subject of physiology or medicine, and the fifth prize to the person who has achieved the most for the promotion of the cause of peace throughout the world. These prizes, which are all open to all the world, will be awarded by the various Swedish academies, except the prize for the propagation of peace, which is left in the hands of a committee to be elected by the Norwegian Parliament.

Football and Life Insurance.—The editor of the *Medical Examiner*, referring to the destructive game of football, says that those who engage in it are not fit subjects for life insurance. He says that recent changes in the rules have not reformed the practice of the players sufficiently to make the game safe for those wishing to avoid a probable life injury or sudden death. He quotes from Dr. Amidon, who carefully compiled from *The Lancet* a table of casualties occurring in Great Britain in a single year. The total was one hundred and eight "grave injuries," among which were one severe injury, internal, resulting in death in two days; six abdominal injuries, fatal; one accident followed by lockjaw and death; twenty fractures of collar bones, three of legs, three cases of concussion of brain, and various other injuries of spine, and internal injuries.

Dr. Belmont Bogert, who began work at Bellevue Hospital on the morning of January 1st, as ambulance surgeon, fell while jumping from the ambulance on the evening of the same day, and broke his leg.

New Journals.—With the new year come the new medical journals. As one looks over the vast and not always unruffled ocean of medical journalism, one recalls the words of Goethe—

"Geburt und Grab,
Ein ewiges Meer,"

for if many medical journals are born every year, many also pass away "like snaw wreaths in thaw." Yet enough remain (particularly in France and in the United States) to make one inclined to say, with John Abernethy, on entering his crowded lecture room on the 1st of October: "God help you, gentlemen; what is to become of you all?"—*British Medical Journal.*

The Solution of the Dispensary-Abuse Problem.—Charity begins at home, and it is time the charitable hands of the men of the medical profession who are active in charity work in hospitals and dispensaries were somewhat stayed for the benefit of those of their own calling.—*Cincinnati Lancet-Clinic.*

Medical Missionaries.—The number of medical missionaries in the world, says the *Maryland Medical Journal*, is 460, an increase of 122 in five years. Of these, 168 are in China, 165 in India, 44 in Africa, 34 in Syria and Turkey, and a smaller number in each of nearly a score of other countries. More than 340 are men and about one-third of that number women. The United States has 246 in the field; Great Britain, 174; Canada, 21. The American Presbyterians lead with a total of 71; the American Methodists follow with 55. Not to be outdone by Artemus Ward, who was ready at the call of duty to sacrifice all his wife's relations, we doubt not the medical profession in this land alone would bid Godspeed to as many more earnest workers, could they but be induced to offer themselves up for the good cause.

Proposed Sale of Two Famous Institutions.—It has been suggested as a measure of economy that the Salpêtrière and the Bicêtre in Paris be closed and the buildings sold. The inmates, to the number of about five thousand, could then be pensioned for thirty cents a day. As their support in the institutions now costs sixty cents a head a day, a saving of about half a million dollars per annum would be effected. In addition to this, the sale of the land occupied by the buildings would bring in about $6,000,000, the in-

come of which would be nearly a quarter of a million dollars more. There are said to be some eight thousand aged poor in Paris unable to obtain admission to the Salpêtrière, and the saving effected by the proposed measures would furnish enough to pension each of these at the same rate of thirty cents a day.

Medical Shepherds in Australia.—A writer in a London newspaper states that a number of young medical men, who emigrated to Australia some years ago with the idea that they would soon build up big practices there, are engaged at the present time as shepherds.

Besieging a Dispensary.—Some mischievous liar recently set afloat a story that two negro children had been kidnapped by the physicians of the St. James Dispensary in Savannah, and carried into the building and killed. The story soon spread among the colored population and was confirmed apparently by some school children, who said that they had climbed into a tree which grows near one of the dispensary windows, and had seen the bodies of the two children on a table, and that white men were standing around them cutting them up. A mob of negroes soon gathered in front of the dispensary building, and were dispersed by the police only after several of the ringleaders had been arrested. The excitement continued for several days, and crowds of excited colored men and women assembled repeatedly in front of the building. The colored teachers in the schools and the pastors of the colored churches have been asked to use their influence to disabuse the minds of the negroes of their belief in the vivisection practices of the dispensary doctors. It will probably be a long time before a pickaninny ventures to pass the door of St. James Dispensary after nightfall.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on December 23d, the president, Dr. W. E. Hughes, in the chair. Dr. Hughes reported two cases presenting jaundice and terminating fatally, in which post-mortem examination disclosed no adequate cause for death, and which for the want of a better name he designated Weil's disease. Dr. Joseph Sailer presented a communication detailing "Results of Laceration of Brain Substance." He exhibited sections showing a coarse fibrous formation and increase in neuroglia cells in the line of aseptic puncture of cat's brain three days after death. Dr. Joseph MacFarland read a paper entitled "Pneumothorax with Discovered Perforation," and he presented an illustrative specimen from a fatal case of pulmonary tuberculosis. Dr. M. Ostheim reported a case of carcinoma of the stomach, ulcerating into the liver, in which basophile cells were found in blood vomited during life. Dr. C. S. Potts exhibited the spinal cord from a young man, whose right leg had been amputated some eighteen months previously on account of sarcoma. Several vertebræ were partially disorganized, and numerous tumor masses were found in the spinal canal external to the dura mater, compressing the cord in a number of situations. Dr. David Riesman exhibited a fœtus, eight days old, in which the only lesion found post mortem was hemorrhage into the suprarenal capsules. On the right side was a congenital inguino-scrotal hernia with a patulous internal ring.

Philadelphia Neurological Society.—A stated meeting of the Philadelphia Neurological Society was held on December 20th, the president, Dr. C. W. Burr, in the chair. Dr. James Hendrie Lloyd exhibited a marked and typical case of astasia-abasia. Dr. D. L. Edsall reported, by invitation, a case of "Disassociation of Sensation of the Syringomyelic Type in Pott's Disease." Dr. W. E. Hughes read, by invitation, a report of "Two Cases of Tumor in the Pituitary Body," in neither of which were symptoms of acromegaly present. Dr. A. A. Eshner presented "A Further Communication upon a Case of Meningitis." There had been present during life some symptoms of posterior spinal sclerosis, some of paretic dementia, and others that could not be explained by either of these diseases. Death resulted from an enormous cerebellar hemorrhage, rupturing into the ventricles, and post-mortem examination disclosed a generalized meningo-encephalitis. Dr. E. R. Schreiner reported, by invitation, a case of arsenical neuritis developing in the course of treatment of chorea with Fowler's solution. In the discussion the question was raised whether the lesion present under circumstances of this kind is not a degeneration rather than an inflammation, and whether also the spinal cord may not sometimes be involved, as well as the peripheral nerves.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on December 22d, the president, Dr. James Tyson, in the chair. Dr. Joseph Price read a paper entitled "Operative Detail in Appendicitis," in which he recommended the introduction of sutures into the appendix before division of the portion to be removed. Dr. William F. Arnold, passed assistant surgeon in the United States navy, read, by invitation, a paper entitled "Some Personal Observations on the Bubonic Plague." Some doubt was cast upon the specificity of the bacillus described by Kitasato as the causative factor of the disease, and a word of commendation was expressed in favor of Yersin's antitoxic serum. Dr. Milton B. Hartzell reported "A Case of Epithelioma in a Boy of Fourteen." Dr. Edward Jackson made a report of "A Case of Ivory Exostosis of the Orbit," and exhibited several specimens. Dr. J. B. Learned, by invitation, made some remarks on the induction of sleep through fatigue induced by various muscular exercises during recumbency in bed.

Dangerous Patent Medicines. — The Ohio State food and dairy commissioner, Mr. Blackburn, has incurred the anger of certain unscrupulous patent-medicine men and newspaper proprietors by his honest efforts to enforce the law. He has brought suit against the manufacturers of various proprietary medicines, on the ground that the medicines contain poisons or narcotic drugs, and that, according to the law of the State, the packages in which they are inclosed should be labelled accordingly. The owners of the quack

medicines naturally have not taken kindly to this ruling, and in many instances have withdrawn their goods from sale in the State. With the goods went the advertisements in the newspapers, which meant a loss of revenue to the publishers. The latter complained, and the commissioner then appeared before an association of newspaper publishers, and demonstrated to them very clearly the danger of dispensing morphine, cocaine, chloral, and other poisons without a word of warning to the ignorant purchasers of these patent medicines. He recited many instanes of death or the formation of an enslaving drug habit directly due to the use of quack remedies, and succeeded in convincing his hearers that the law was a wise one, even if it did bear a little heavily for the time being on the profits of their publications.

The Deadly Roentgen Rays.—A jury in Elmira last week acquitted of murder a man who was on trial accused of this crime. The man whom the accused shot was said to be improving a month after the shooting, when the *x*-rays were used to locate the bullet which was in the brain. Death followed, and the defence alleged that the death was the result of the action of the Roentgen rays, and that the wounded man would certainly have lived had no attempt been made to locate the bullet.

Food Adulteration in Connecticut.—The board of control of the Connecticut agricultural experiment station has made a report to Governor Cooke, showing the results of the second series of examinations of articles of food made under its authority. The tests were made on samples bought in eighteen villages and cities of the State. Including among the adulterated articles any food treated with borax, salicylic acid, or other preservatives, the summary shows that ten hundred and sixty-three samples were tested, of which three hundred and three, or more than twenty-eight per cent., were adulterated.

Anthrax in Pennsylvania.—The State board of health recently called the attention of Governor Hastings to the outbreak of anthrax in Pennsylvania, caused by handling imported hides in the tanneries at Falls Creek. The governor has communicated with the treasury department at Washington, requesting that hides carrying that disease may be excluded from our ports or so disinfected as to destroy the germs of anthrax. The consular officers had already been instructed to refuse authentication of invoices of hides of neat cattle from districts in which anthrax is known to exist.

A Parisian Lady Specialist.—A lawyer writes to *The Lancet*, asking who was Dr. Marion Sims. Being a layman, he says, he had not heard of him, "but," he continues, "I happen to have seen the other day a circular bearing the name of a chemist not unknown, describing something invented by the 'late Dr. Marion Sims, a famous Parisian lady specialist.' I once heard of a man who took Marion Crawford down to dinner, and found her a most charming and accomplished lady. If this is a parallel case, it might amuse your readers to hear of it."

To Determine Sex.—Professor Schenk, well known to American students as the head of the Embryological Institute in Vienna, has announced that after twenty years' study of the question he is now prepared to tell how to determine and regulate the sex of offspring, and will do so in a communication to the Academy of Sciences.

A Doctorless City.—According to *Petermann's Mittheilungen*, there is a city of sixty thousand inhabitants in Syria, not far from Latakia, in which there is not a single physician. The name of this unfortunate place is Hamah. As is the case with most of the towns in that country, diseases of the eyes are exceedingly common, and an oculist who is willing to rough it and to suffer many discomforts could doubtless gather in numerous shekels.

Fire at Deer Island Hospital.—The easterly wing of the hospital building at Deer Island, Boston Harbor, was damaged by fire on December 11th, to the extent of $6,000. The fire was due to the overturning of a gasolene lamp, and demonstrated the insufficiency of the water power on the island. There were no casualties among patients or attendants.—*Boston Medical and Surgical Journal.*

The Health of New York.—The late president of the health board, in his final report to the mayor on the work of his department, gives the estimated population of old New York as 1,990,562. The deaths during the year were 38,857, equalling a rate of 19.2 per thousand, the lowest in the history of the city. Decreases are reported in the deaths from diarrhœal diseases and in infant mortality, directly traceable, the health officers say, to the improved sanitary conditions which prevailed during the year.

Inspection of the Island Institutions.—Governor Black recently visited the various charity institutions on the islands in the East River. The Hart's Island buildings he found old, unventilated, and crowded, and on Ward's Island also there was need of more and better accommodations. He was greatly pleased, however, with the House of Refuge.

Cost of the Indian Famine.—It is officially announced that the recent famine cost the Indian treasury $4,000,000, while loans to agriculturists and suspensions of taxes absorbed $2,000,000, irrespective of charitable contributions approximating $8,750,000.

Death from Cocaine.—Dr. Edward J. Sherow, a graduate of the College of Physicians and Surgeons of the class of 1890, twenty-eight years of age and a native of Sing Sing, N. Y., died on New Year's morning, in this city, from a supposed overdose of cocaine. It is said that the cocaine habit was contracted through application of the drug to the nasal mucous membrane for the cure of a catarrhal affection.

The State and Local Boards of Health of Ohio.—The eighth annual meeting of these boards will be held in Columbus, Ohio, on Thursday and Friday, January 20th and 21st, under the presidency of Dr. Thomas C. Hoover, president of the Ohio State board of health.

Reviews and Notices.

THE NEW PSYCHOLOGY. By E. W. SCHRIPTURE, Ph.D., Director of the Yale Psychological Laboratory. Published by Walter Scott, Ltd., London, and Imported by Charles Scribner's Sons, New York.

THIS volume forms one of the "Contemporary Science Series," which physicians have learned constitute a very important addition to their libraries. During the past few years the study of psychology has had a new interest for medical men because they have seen how closely in touch the experimental psychologist and the experimental physiologist are in their work, and what applicable bearing their conclusions have upon clinical medicine. The new psychology of the author is experimental psychology. The volume of five hundred pages is divided into five parts and eight appendices. The first is taken up with a consideration of methods, the second of time, the third of energy, the fourth of space, and the fifth of past and present. In the last chapter the author points out the fundamental difference between the science of the Greeks and the science of to-day. He pays a fitting tribute to Fechner, Helmholtz, Wundt, and other of the early prospectors to whom honor is properly due. The concluding chapter, the one entitled "The Present Situation," is one that might have been, we believe, properly and fittingly omitted. The author has a lively, convincing style, and has apparently striven to make everything subservient to lucidity. We know of no better up-to-date *résumé* and guide of physiological psychology. We have had much pleasure and profit in reading it, and we warmly recommend it to members of the profession who are interested in this branch of physiology or who wish to have their interest inspired.

THE PSYCHOLOGY OF THE EMOTIONS. By TH. RIBOT, Editor of the *Revue Philosophique*. Published by Walter Scott, Ltd., London, and Imported by Charles Scribner's Sons, New York.

THIS is likewise one of the volumes of the "Contemporary Science Series," but it is not the new psychology. It comes from the pen of one whose reputation for clear thinking and for logical statement is as widespread as the recognition of the science of psychology. The psychology of states of feelings is one of more than ordinary interest to the neurologist and alienist, and the time is opportune for the appearance of a short work such as the one before us. The volume is made up of an introduction, which is devoted to the evolution of the affected life, and of fourteen chapters. In the first part, chapters are devoted to physical pain, to moral pain, to pleasure, to morbid pleasures and pains, to the neutral states, and then a chapter entitled "Conclusions on Pleasure and Pain" is given. This mode of handling commends itself, both to the student and to the desultory reader. The remainder of Part I. is concerned with the emotions, feelings, and the feelings and the associations of ideas. Part II., devoted to special psychology, considers the instinct of conservation in its psychological form, fear, anger, sympathy, and the tender emotions, the sexual instinct, the social and moral feelings, the religious sentiment, the æsthetic sentiment, the intellectual sentiment, etc. Finally, the author commends himself to our graces by stating his conclusions in five brief pages. It would be out of place in a medical journal to attempt to make a critical analysis of so comprehensive a work as this, and we shall content ourselves with the statement that close study of its pages will fully reward while it absorbs the reader.

THE NORMAL AND PATHOLOGICAL CIRCULATION IN THE CENTRAL NERVOUS SYSTEM. By WILLIAM BROWNING, M.D. Philadelphia: J. B. Lippincott Company.

THE author, who has made himself favorably known by his work on the encranial circulation, has gathered together in a volume of one hundred and seventy pages a number of essays that have been already published in medical journals or read before medical societies. They are on such diverse topics as "An Examination of the Spinal Efferents for the Cerebro-Spinal Fluids," "On the Remains of a Foramen Spheno-Temporale in Man," "Lumbar Puncture for the Removal of Cerebro-Spinal Fluid" (which procedure, by the way, the author was one of the first to use in this country and to point out the worth of as a diagnostic agent), and "A Case Suggesting Multiple Sclerosis, but Due to Cranial Aneurism." There are altogether eighteen short sections, some of interest to the anatomist and morphologist, others to the clinician and physiologist. We have nothing but words of praise for the spirit of Dr. Browning's little volume, and the same may be said for a large part of the subject matter. Some of the latter, however, is rather perfunctory and unfinished, and it would contribute more to the author's reputation if it was withheld for a time. Notwithstanding this, the book is one that we warmly recommend to our readers as a suggestive and instructive collection of brief essays. The author shows his prentice hand of bookmaker on many pages. Involved sentences, faulty grammatical construction, annoying lapses of sequence, the interpolation of non-pertinent matter, are to be observed on more pages than one; but we shall cite only page 170. There is one more point to which we may call attention. It seems to us that it is incumbent upon a writer, when he cites the name of another writer, to cite at least the initial of his surname. We believe that he owes that to the man from whom he borrows. In the preface to his book, Dr. Browning says that the subject of normal pressure in the dural sinuses has been so fully treated by Hill that anything thereon seems superfluous at the present time, while, in the chapter on the arrangement of the supracerebral veins in man, Alexander Hill is frequently referred to. One who is not intimately familiar with anatomical literature would naturally infer that the first Hill was the second Hill and *vice versa*. Perhaps we have said enough to suggest that this is not the case.

A SYSTEM OF MEDICINE. By Many Writers. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College. Volume IV. New York: The Macmillan Company. 1897.

THE present volume of this system treats of "general diseases of obscure causation" and of "diseases of alimentation and excretion." In the first category are all the rheumatic and gouty affections, rickets, osteomalacia, and diabetes; in the latter are diseases of the stomach (among which the editor has curiously enough included seasickness and mountain sickness), subphrenic abscess, diaphragmatic hernia, enteroptosis, diseases of the bowels, diseases of the peritoneum, abdominal diagnosis from a gynæcological standpoint, diseases of the mouth, diseases of the œsophagus, and shock and collapse. The last-named article is a well-written and interesting one, but we cannot see why its subject should have been placed in the group of alimentary diseases when it is clearly a nervous affection. However, consistency in classification is a matter of slight importance in a work of this kind. The subjects treated of in this volume are interesting in themselves, and are handled in an interesting manner by competent men. There is the same curious uncertainty in regard to the number of this volume that we noticed in reviewing the preceding one; on the title-page it is called volume iv., but it closes with the legend, "End of Vol. III."

MORAL PRINCIPLES AND MEDICAL PRACTICE, THE BASIS OF MEDICAL JURISPRUDENCE. By REV. CHARLES COPPENS, S.J., Professor of Medical Jurisprudence in the John A. Creighton Medical College, Omaha; Author of Text-Books on Metaphysics, Ethics, Oratory, and Rhetoric. New York, Cincinnati, and Chicago: Benziger Brothers. 1897.

THIS book contains the substance of lectures delivered by the author to the students of the John A. Creighton Medical College of Omaha, Neb. As would be naturally expected, the various subjects are treated of purely from the standpoint of the moral teachings of the Catholic Church, which are, of course, accepted in the main by all right-minded men of any or no dogmatic belief. We find nothing new, however, that is of value; the moral teachings are old, and the scientific are generally valueless. It would have been better, we think, had the final chapter on "Hypnotism and the Border Land of Science" been omitted, for there the author abandons his place as a teacher of morality and ventures into the domain of pseudo-science, hazarding the opinion, or rather dogmatically asserting, that the marvels of spiritism and the like are the work of devils and degraded spirits. It is a strange revelation to read such absurdities penned by a man

who claims to teach science. The authority of the author as a teacher in a regular school of medicine is seriously weakened also by the following statement, which we find on page 112: "In the allopathic [*sic*] school of medicine, in which you are being educated, the leading principle is: 'Contraries are cured by contraries—*Contraria contrariis curantur.*'"

Studier over Gummös (Tertiær) Syfilis. Af Kristian Grön. Læge ved Kristiania Kommunale Sygehns' afd. Sorgenfri. Kristiania: Steenske Bogtrykkeri. 1897.

This is a painstaking study of tertiary syphilis as regards especially its "frequency, point of origin, symptoms, and probable causes." Among other points of interest discussed by the author is the fact that the treatment of syphilis seems to be as successful in Norway as elsewhere, although mercury is very seldom employed.

Lippincott's Pocket Medical Dictionary. Including the Pronunciation and Definition of Twenty Thousand of the Principal Terms Used in Medicine and the Allied Sciences, together with Many Elaborate Tables. Edited by Ryland W. Greene, A.B., Editor of Lippincott's Medical Dictionary. Philadelphia: J. B. Lippincott Company. 1897.

This is apparently an abridgment of the larger dictionary recently issued by the same publishers. It seems well adapted to meet the wants of the users of pocket dictionaries. Most of the usual medical terms seem to be included, though we miss some of the more recent ones.

Transactions of the Michigan State Medical Society for the Year 1897. Volume XXI.

The meeting of the society of which this volume is a report must have been of an unusually interesting character, judging from the number and variety of papers presented. Considerable attention was paid by the contributors to the social and legal relations of the physician, and there was much plain and sensible talk on both subjects. Dr. Roswell Park, of Buffalo, made the address on surgery, which is in full keeping with his well-known ability in treating a broad subject.

Transactions of the State Medical Society of Wisconsin for the Year 1897. Volume XXXI. 8vo, pp. 667. 1897.

This volume contains the papers and discussions of the last annual meeting, held at Racine on May 5th. The papers are of a thoroughly practical character and have the additional merit of brevity, which has enabled the committee of publication to present a volume compassing a wide range of interesting subjects.

The Practice of Surgery. A Treatise on Surgery for the Use of Practitioners and Students. By Henry R. Wharton, M.D., Demonstrator of Surgery in the University of Pennsylvania, and B. Farquhar Curtis, M.D., Professor of Clinical Surgery, New York Post-Graduate Medical School. 8vo, pp. 1,240. Philadelphia: J. B. Lippincott Company.

There is a consistency in this work which will appeal most directly to those who need it. It is, in short, a surgery for the practitioner which gives him the information he needs in treating such cases as may come to him in his general line of work. The selections are judiciously made, and the apportionment of space to given topics is seemingly in accordance with their importance. Viewed as a whole, the work is an admirable condensation of a very broad subject. The reader profits by this in more ways than one. The authors, in their efforts to express the mere facts, get at the point at once, and oftentimes in one sentence express the contents of pages of the more elaborate treatises. Instead of lengthy discussions being given, the convictions of the authors are simply stated, to the eminent satisfaction of the student. The practitioner receives all the information necessary for a diagnosis and treatment of all the ordinary cases in surgery, but more especially the emergency ones. For the more difficult cases he has sufficiently impressive lessons of the dangers of attempting what he may not be able to perform, in which case he can the more properly and impartially refer the patient to the expert surgeon. Another feature of this admirable work is the large number of fine illustrations, most of which are from original photographs, and show many typical cases of surgical disease. The authors merit the heartiest congratulations for the successful manner in which they have fulfilled their intention. It is really the practitioner's text-book on surgery.

Diseases of the Gall Bladder and Bile Ducts. By A. W. Mayo Robson, F.R.C.S., Member of Council and Hunterian Professor of Surgery and Pathology, Royal College of Surgeons of England. 8vo, pp. 150. New York: William Wood and Company. 1897.

A great deal of practical information is compressed in the small volume before us, which is a condensation of a course of lectures on the subject delivered before the Royal College of Surgeons. The work may be divided in three principal parts, which deal, first, with the inflammatory affections of the gall bladder and ducts; secondly, with tumors of these organs; and thirdly, with the surgical treatment of gall stones. The first two conditions are exhaustively considered from a pathological standpoint, and several curious lesions and anomalies are illustrated. The various operations are very intelligibly described, and all the necessary details of technique are so clearly given that even a novice can grasp the indications in any given class of procedure. This is certainly a feature of the brochure which will commend itself to every student. The author is fortunately able to state that he has never lost an operation for non-malignant disease, and proves the fact by an elaborated tabular statement in the appendix.

Tuberculosis of the Genito-Urinary Organs, Male and Female. By N. Senn, M.D., Ph.D., LL.D. Illustrated. Philadelphia: W. B. Saunders. 1897.

There are many features of this book which make it of more than passing interest. The field is a comparatively new one, and some of the views expressed are also new, while others are at variance with past teachings. To those who have not kept well abreast of current literature bearing upon genital tuberculosis, much contained in these three hundred and ten pages will come like a revelation. By those working every day in the same field the lucid descriptions and detailed accounts of personal cases will be read with profit and pleasure. No doubt, as the author implies, much of the tuberculosis originating in the external genitals has been confounded with processes due to other causes. Fifty per cent. of uro-genital tuberculosis in the male has its origin in the epididymis. The proposition will be a surprise to many, though supported by the investigations of Councilman. The work is divided into eleven parts: two devoted to the various male organs, six to female organs, and one each to the bladder, ureters, and kidneys—the latter naturally consuming the greatest space. The print and paper are good. The subject matter is quite in keeping with the previous well-known work of the author.

Bath as a Health Resort. Published by the Bath Corporation.

This is a handy guide to Bath, republished on the occasion of the opening of the new pump room a short time ago. The book is well illustrated, and gives a good idea of the place and of its health-giving air and waters.

Cutaneous Medicine. A Systematic Treatise on the Diseases of the Skin. By Louis A. Duhring, M.D., Professor of Diseases of the Skin in the University of Pennsylvania; Author of "A Practical Treatise on Diseases of the Skin" and "Atlas of Skin Diseases." Part II. Philadelphia: J. B. Lippincott Company. 1898.

Part I. of this work we have already noticed. Whatever there was of a favorable nature in what we said may be repeated of the present volume, which deals with the classification, "Anæmias, Hyperæmias, and Inflammations." The author has done well to make the subdivisions of the work result in a series of volumes any one of which can be readily held in one hand while being read. The page numbers are, however, continuous, so that if it is desired the completed work may form a single volume. The classification referred to begins on page 223, and "Inflammation," starting with page 247, leaves but little space devoted to anæmic and hyperæmic states. Naturally eczema takes up most of this

chapter, and the numerous illustrations embracing all varieties have been selected with evident care, based upon experience of what the average reader most requires. The chapter on dermatitis herpetiformis is shorter than one would have looked for, for considering that it is so intimately associated with the author's name. It is illustrated by a number of plates, and the writer's views are made plain and concise. The work is destined to take a very high rank in the world's dermatological literature.

De Dovstumme i Norge. Af V. Uchermann, Professor ved Kristiania Universitet. Kristiania: Alb. Cammermeyer.

This is a very exhaustive study of deafmutism in Norway, including the etiology, symptoms, diagnosis, pathology, and treatment, with a review of the social relations of the afflicted, the statistics of deafmutism, etc. The work is in three volumes—one of text, one of tables, and a third of colored charts—is a monument to the enormous industry of Professor Uchermann, and a contribution of great value to the literature of this interesting subject. A brief abstract in French renders the material of service to those who cannot read the Norwegian.

L'Acromegalia nei Suoi Rapporti coll' Organo Visivo. Per le Dott. Francesco Denti, Primario Oculista nell' Ospedale Maggiore; Docente Universitario. Milano: Tipografia del Riformatorio Patronato. 1897.

This is one of the monographs bound up in a volume containing the clinical report of the ophthalmic section of the Ospedale Maggiore in Milan. Other subjects discussed are sympathetic ophthalmia, diseases of the conjunctiva, glaucoma, cataract operations, subconjunctival injections of corrosive sublimate, diseases of the optic nerve and retina, bulbar and extrabulbar neoplasms, and enucleation of the eyeball. The author has brought together an interesting collection of well-written memoirs.

Lectures on the Action of Medicines, Being the Course of Lectures on Pharmacology and Therapeutics, Delivered at St. Bartholomew's Hospital, during the Summer Session of 1896. By T. Lauder Brunton, M.D., D.Sc., LL.D., F.R.S., Fellow of the Royal College of Physicians, Associate Fellow of the College of Physicians of Philadelphia, Honorary Member of the Pharmaceutical Society, Physician and Lecturer on Pharmacology and Therapeutics to St. Bartholomew's Hospital. New York: The Macmillan Company. 1897.

The students at Bart's are to be warmly congratulated if they have such lectures as these to listen to, for not only must the listening be a pleasure but the knowledge so gained cannot but make them better physicians. But we who have never heard the lectures are also to be congratulated that the opportunity is ours of reading them in this convenient form. The book does not contain all the science of materia medica and therapeutics, but it contains what is far better for the practitioner-student, a most interesting *causerie* on therapeutic agents and how they act, with incidental allusions to the treatment of many minor and major ills. The book can be read from beginning to end with profit, or it can be browsed in with entertainment. The fact that the colloquial style of the lectures has been preserved has much to do with the ease and pleasure with which the book can be read and studied.

Dr. Mendini's Hygienic Guide to Rome. Translated and Edited by J. J. Eyre, M.R.C.P., etc. London: The Scientific Press, Limited. 1897.

The account of the hygienic conditions in Rome given by the author of this little book will come as a surprise to most people who have preserved the traditions of the deadly "Roman fever" and of the pestiferous germ-laden air of the Roman Campagna. It is time these false notions were dispelled, and we welcome Dr. Mendini's guide as an aid to this end. The author shows by the health statistics of the five largest Italian cities that Rome has the lowest mortality rate, although it is charged with the deaths of all the peasants from the Campagna who die in the hospitals in the city. Of the large cities of the world only London, Berlin, and Paris (and now New York) present a more favorable showing than Rome in this respect. The author asserts with great positiveness that there is absolutely no danger from malaria in the parts of Rome where visitors are domiciled, and every one knows the abundance and purity of the water supply. The book contains a great deal of useful information as to what are the healthiest portions of Rome, and also directions concerning the mode of living for invalids and tourists who make a sojourn in the Eternal City.

Contribution à l'Étude de l'Hémothorax Traumatique. Par le Dr. Antonio Figueiredo, Médecin de l'Hôpital de Sainte-Elisabelle, à Bahia; Membre Fondateur de la Société de Médecine et de Chirurgie de Bahia. Paris: A. Maloine. 1897.

This monograph on traumatic hæmothorax is based on a study of five cases. The histories of these are given in detail, and following each the author presents a discussion of the special diagnostic problems involved, and also enters upon the question of prognosis as this is influenced by the general condition of the patient. The study is carefully made, and shows that Dr. Figueiredo is not only a discriminating observer but an acute reasoner.

Pathological Technique. A Practical Manual for the Pathological Laboratory. By Frank Burr Mallory, M.D., and James Homer Wright, M.D. Philadelphia: W. B. Saunders. 1897.

This book is designed for practical use in pathological laboratories, both as a guide to beginners and as a source of reference for the advanced. There are one hundred and five excellent illustrations in the text. In the parts devoted to bacteriology and to pathological histology those methods and formulæ have been selected by the writers which have been found of the greatest service in practical work.

Essentials of Bacteriology. Being a Concise and Systematic Introduction to the Study of Micro-Organisms, for the Use of Students and Practitioners. By M. V. Ball, M.D. Third Edition, Revised. Philadelphia: W. B. Saunders. 1897.

This practical and useful compendium has just appeared in its third edition. The article on "Diphtheria" has been carefully revised, and the latest knowledge concerning the antitoxin treatment added.

Transactions of the American Surgical Association. Volume XV. Edited by De Forest Willard, A.M., M.D., Ph.D. 8vo, pp. 602. Philadelphia: W. J. Dornan.

This volume is full of unusually good things, among which may be mentioned the admirable address of the president, Dr. J. Collins Warren, of Boston, on the "Influence of Anæsthesia on the Surgery of the Nineteenth Century;" the addresses on the unveiling of the Gross statue at Washington; and the papers by Drs. Charles A. Powers, Edmond Souchon, Dudley P. Allen, and others. Among the illustrations is a fine one of the Gross monument as it now stands.

A Manual of Clinical Diagnosis by Means of Microscopic and Chemical Methods. By Charles E. Simon, M.D., Late Assistant Resident Physician, Johns Hopkins Hospital. Second Edition. 8vo, pp. 563. Philadelphia and New York: Lea Brothers & Co.

The second edition of this work bears very substantial evidences of thorough revision and is in all respects entirely up to date. This is saying a great deal, considering the rapid progress made in the special departments of research of which it treats. The volume is the outcome of the new methods of clinical diagnosis by bacteriological and chemical examinations, and duly records the recent triumphs in the more exact lines of pathological research. The author very truly says, in view of practical and useful work already done in this line, that it is inconceivable that a physician nowadays can rationally diagnose and treat diseases of the stomach, intestines, kidneys, liver, and other vital organs without laboratory facilities. As proof of the faith in him he offers a very practical argument in the book itself. To the progressive student every chapter is of the greatest interest in stimulating him thoroughly to investigate every case. "The Microscopic and Chemical Examination of the Blood," forming the first chapter, is an admirable study of an intensely interesting and complex subject. The secretions of the mouth, the gastric juice, fæces, sputum, and urine

are treated with like thoroughness, breadth, and detail. To any one who may not have had his attention directed to the practical utility of the examinations in question the work will be a revelation, while to the new-school investigator it will be a fresh incentive to still more useful work in the same directions. The illustrations are well made, and some of the colored plates are works of art.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 27, 1897.

ARTHUR M. JACOBUS, M.D., PRESIDENT.

The Method of Operating for Small Epitheliomata of the Lip.—DR. CHARLES N. DOWD read a paper on this subject. He said that of a series of 277 operative cases reported by one observer 35 per cent. resulted fatally by recurrence, and 5 per cent. by operation; while in 106 cases, or 42.2 per cent., there was survival for three or more years without recurrence. But these figures hardly indicated the present status of the subject. These patients usually consulted the surgeon at an early stage, and diagnosis was readily made in most instances. The ordinary treatment was by excision of a wedge-shaped piece of the lower lip and sewing together the edges of the wound, yet the disease recurred in many cases so treated. The glands were usually involved in the following order: (1) those on each side under the lower jaw; (2) those in the floor of the mouth; (3) the superficial group between the cheek and the hyoid bone; and (4) those on both sides of the neck down to the clavicle. Submaxillary enlargement, he said, was usually first noticed in one or more lymph nodes lying contiguous to the submaxillary salivary gland. These infected glands could be easily palpated if the finger was passed into the mouth down to the lower margin of the body of the jaw, just in front of the facial artery, counterpressure being made with the fingers on the outside. Unless such an examination was made, even an ordinarily careful diagnostician was liable to overlook the glandular involvement.

What Operation Recommended.—The method of removal recommended was an incision under the body of the jaw, three-fourths of an inch to one inch in length, reaching forward from a little in front of the facial artery. It should be carried down to the submaxillary salivary gland. The lymph node most often involved would be found just at the anterior border of this gland. If the posterior border of the mylo-hyoid was retracted, the gland would be exposed in the incision and could be easily removed. Through this incision the glands in the immediate vicinity could also be readily examined and, if necessary, extirpated. This procedure should not prolong the period of healing, and it should be done in all instances in which glandular involvement was detected. In the removal of the growth itself from the lip, a good-sized piece of tissue should be sacrificed. A large portion of the lip could be removed without making an unsightly deformity. Two patients were presented to illustrate the good cosmetic effect obtainable even by this more radical method of operating. From one half of the lip had been removed and from the other three-fourths of the lip, yet in both there was very slight disfigurement.

DR. DANIEL LEWIS said that, speaking in general terms, his own experience was that when the operation was done before the involvement of the lymph nodes, ninety-five per cent. were permanently cured; and that when these nodes had become infected prior to the operation recurrence took place in ninety-five per cent. of the cases. He agreed with the reader of the paper that it was not always necessary to open up the tissue under the neck and search for these glands, because they could be invariably detected by palpation performed in the manner described.

An Elliptical Incision Preferable. — For a long time past, instead of making a V-incision, he had used an elliptical one, because it was a common experience after the V-incision had been used to have the upper stitch give way during the healing process because of the unequal tension on the sutures. If an elliptical incision was used, the tension was distributed more uniformly. In operating upon these cases he employed only a pair of curved scissors. A single cut was made on either side, the epithelioma removed, and the wound brought together with horsehair sutures. Under a dressing of aristol-collodion primary union usually took place. The whole secret of success consisted in operating early. The diagnosis could be made largely by the age of the patient; any such lesion of the lip occurring in a person of fifty years or more of age, and resisting the ordinary applications, was either a cancer or at least a precancerous disease.

More Radical Treatment Favored. — DR. WILLY MEYER said that he believed it was the duty of the surgeon in every case of cancer of the lip, unless it was seen at an extremely early stage, to enter and inspect both submaxillary triangles. We could not always feel an extremely small gland, even by the method advised in the paper; hence it was very much better for the patient's future to open up both submaxillary triangles and remove in one mass the submaxillary salivary gland and lymph glands and all the fat. The wound should then be closed except a small opening, and the cancer of the lip excised. These wounds almost invariably healed as quickly as the wound in the lower lip. He had operated in this way about six years ago upon a man aged sixty-two, taking away the entire lip and many of the glands. Three years later he had been able to exhibit the patient before the New York Surgical Society, without any recurrence.

DR. PARKER SYMS agreed with the reader of the paper regarding the importance of making the bimanual examination for detecting all swellings below the mouth, yet he was inclined, with Dr. Willy Meyer, to take a more radical position than the author, and advise the removal of the glands in all cases. It was conceivable that even those glands which were too small to be palpable might be in the incipient stage of cancer. The results obtained in the very radical operations advised by Dr. Meyer and Dr. Halsted for cancer of the breast were a sufficient justification of this position.

The Improvement of General Anæsthesia by Adapting the Boiling-Point of the Narcotic to the Temperature of the Body (Schleich). — DR. WILLY MEYER said that it was fair to assume even now that one out of every two thousand still dies under chloroform anæsthesia, and one out of ten thousand under ether anæsthesia. It was this uncertainty regarding general anæsthesia that had led many surgeons to strive to perfect cocaine or other local anæsthesia. Dr. C. L. Schleich, of Berlin, reasoning from experiments on animals, was of the opinion that the absorption of a general anæsthetic is dependent on (1) the surrounding temperature, and (2) the boiling-point or maximum of evaporation of the anæsthetic.

The Physics of Ether and Chloroform Narcosis. —If a person inhales an anæsthetic having its point of maximum evaporation at 59° F., less will be introduced into the blood than if the anæsthetic has a maximum evaporation of 149° F.—*e.g.*, chloroform. If the maximum evaporation of the narcotic approaches the temperature of the body the lungs alone are capable of regulating the elimination, so that exactly as much

is exhaled during expiration as was inhaled during inspiration. This explains the fact that deep narcosis cannot be produced if the maximum of evaporation of the narcotic and the temperature of the body correspond. If, however, the maximum evaporation is 149° F., more of the anæsthetic is absorbed in inspiration than is eliminated in expiration. It must, therefore, be eliminated somewhere else—the heart, kidneys, and liver must be called into action; and this explains why the after-effects on these organs are so much more pronounced after chloroform than after ether. Sulphuric ether having a maximum evaporation of 93° F., at a temperature of 100.4° F. it must expand and distend the pulmonary alveoli. It is this obstruction to respiration which causes a certain degree of cyanosis. Another result is the secretion of mucus and the frequent occurrence of secondary pneumonic infiltration. The pressure of carbonic acid accumulating in the blood partially overcomes the tension of the ether vapor in the alveoli and permits its escape; then the cyanosis disappears and the true ether narcosis begins. It is the slight excess thus remaining in the blood which suffices to affect the brain and produce unconsciousness. Death from ether on the operating-table, therefore, is almost impossible as long as respiration is efficient. On the other hand, it is evident why ether narcosis sometimes has such deleterious effects on the lungs. On account of its high boiling-point chloroform is absorbed by the blood to a greater extent than needed, and in leaving the organism overtaxes all of the parenchymatous organs. Ether, on the other hand, is converted into vapor so rapidly when inhaled into the lungs at the temperature of 100° F., that it would not enter there at all if the alveoli did not first become overfilled with carbonic-acid gas. From the foregoing considerations it is evident that a safe narcotic would be one in which the amount eliminated during expiration would almost equal that absorbed during the previous inspiration.

Why Mixtures are Safer.—It was in this definite and really scientific manner that Schleich started his experiments. In Vienna a mixture of one part chloroform and six parts of ether had been used so extensively as to be known as the "Vienna mixture." It remained for Schleich to show the reason for the greater safety of this and other so-called "mixtures," viz., the lowering of the maximum evaporation more than twenty-seven degrees. Thus the point of maximum evaporation of the A.C.E. mixture is about 119° F.—certainly a good deal nearer the temperature of the body than the point of maximum evaporation of chloroform. This lowering had been almost unconsciously and certainly not deliberately done. No one before Schleich had ever stated the reason for the greater safety of such mixtures. It was important to note in this connection that the term "mixture" is inaccurate, and that we should speak of Schleich's "solutions."

Schleich's Results.—The chief features of Schleich's work are as follows: (1) Our familiar anæsthetics, ether and chloroform, were mixed with a benzin; (2) it was found that by so mixing various ethereal substances the resulting fluid was a true solution in a chemical sense, and not a mere mixture of different ethereal substances; (3) it was ascertained that by changing the proportion of the components one could change the maximum evaporation at will, and so, in a given case, adapt the maximum evaporation of the anæsthetic to the temperature of the patient at the time; (4) these effects were found to hold good, and were verified in cold-blooded as well as in warm-blooded animals; (5) the result is the same whether the anæsthetic was inhaled, given by rectum, or injected subcutaneously; and (6) the result was exactly the same in the human subject as in the lower animals.

Schleich's Solutions.—Schleich recommended three different solutions, made up by volume, and not by weight. Solution No. 1 is composed of chloroform, 1½ oz.; petroleum ether, ½ oz.; sulphuric ether, 6 oz. Solution No. 2 is composed of chloroform, 1½ oz.; petroleum ether, ½ oz.; and sulphuric ether, 5 oz. Solution No. 3 is composed of chloroform, 1 oz.; petroleum ether, ½ oz.; and sulphuric ether, 2⅔ oz.

Author's Conclusions.—Dr. Meyer said that his conclusions, as formulated in this paper, were based on one hundred cases of general anæsthesia observed by him since the middle of last September. They are as follows: Excitement is very rare during the induction of the anæsthesia, and not marked at any time. There is rarely accumulation of mucus, never cyanosis. During the stage of anæsthesia, in spite of the fact that the solution contains sixty to eighty per cent. of sulphuric ether, there is no accumulation of mucus and cyanosis is rare. During this stage the pulse is full and regular, sometimes fuller than before. The respirations are not impaired so long as the narcotizer attends to his work. The type of the respiration is the direct index of the patient's condition. When the respirations become deep and frequent, it indicates the approach of the danger limit. After the anæsthetic is withdrawn the patients awaken more rapidly than after chloroform or ether. More than one-half of Schleich's patients walked home one hour after being anæsthetized. Vomiting occurs, but less often than after other narcotics; it had occurred in forty-four per cent. of his cases. In not a single case was there consecutive bronchitis or pneumonia, although gastrostomy was done on two very wretched persons with very fetid bronchitis. These patients stood the operation remarkably well and the bronchitis was not increased. Albuminuria was found in only four per cent.—a distinct improvement on former experience. A few patients had disliked the odor of the solutions. When administered by artificial light the formation of chlorine gas was very noticeable, and made the attendants cough. This anæsthetic is best administered on one of Esmarch's masks, which has been covered with oil silk and to which a small funnel has been attached. Dr. Meyer thought there could be no doubt that these solutions would soon take the place of chloroform and ether, and that a great boon would be conferred upon suffering humanity through the aid of medical science.

Dr. Ralph Waldo said that Professor Schleich had recently used his anæsthetic solutions in an ordinary towel ether cone. His own personal experience with this method of anæsthesia comprised four cases, in all of which the ordinary cone was employed. A very small quantity of the mixture was used, and the patient was allowed to breathe very little air. The first patient was under complete anæsthesia for fifty-three minutes, and one and one-fourth ounces of the anæsthetic was used. The pulse was 80 at the beginning, and 78, strong, and good at the completion of the operation. The second patient was under the anæsthetic for fifty-three minutes; one and one-half ounces was used; the pulse was 96 before and 84 after the operation. The third patient was anæsthetized for thirty-five minutes: one ounce of the anæsthetic was used; the pulse was 86 before and 80 afterward. The fourth patient was under complete anæsthesia for twenty minutes; the pulse was 90 at the beginning, and 86 after the operation. Thirty minutes after the operation the patient's sensation seemed as good as before, and in less than an hour he went home alone. The rapidity with which the patient came out of the anæsthesia was particularly noticeable when the No. 1 mixture was used. He certainly proposed to continue its use in both public and private practice.

Cyanosis and Excitement in Cases of Nasal Stenosis.—Dr. Franz Torek said that he had employed this method of anæsthesia during the past month, and could confirm everything that had been stated in the paper. The patients recover so rapidly that he had used it sometimes in dispensary practice. For such work Solution No. 1 was most suitable. He had met with cyanosis and excitement in a few cases. It had not seemed to be due to the anæsthetic, however, but rather to disturbance of the respiration, as from nasal stenosis. He had observed this in cases of resection of the lower jaw for carcinoma. When using the anæsthetic by artificial light he had noted a very decided evolution of chlorine gas, though hardly more than with chloroform alone. The method demanded that the anæsthetizer should be just as watchful as with other anæsthetics.

Less Mucus and Less Nausea.—Dr. Parker Syms said that in his limited experience with the new method the longest period of anæsthesia had been two hours and five minutes, in a difficult case of urethral stricture. Anæsthesia had been induced in about five minutes, and the patient had returned to full consciousness within ten minutes after the anæsthetic was withdrawn. Only four and one-half ounces of the No. 1 solution had been used. The shortest period of anæsthesia had been twenty-three minutes, and in this case only three-fourths of an ounce of the anæsthetic solution had been consumed. In his cases there had been very little cyanosis—certainly less than with ether. There had been little or no excitement, and an exceptional freedom from hypersecretion of mucus afterward. A few patients had vomited, but they had been free from the usual annoying nausea. He would certainly continue its use, and felt confident that it would be the future agent for general anæsthesia.

Dr. Emil Mayer asked what had been the experience of the reader of the paper regarding the relative rapidity of evaporation of the three solutions.

Dr. W. McEnroe, comparing our limited knowledge of the new anæsthetic with our large experience with and the demonstrated safety of chloroform and ether, remarked that he knew a man who had given chloroform to six thousand soldiers upon the field of battle, without a single fatal result.

Very Little of the Anæsthetic Required.—Dr. M. L. Maduro expressed his surprise at a former statement of Dr. Meyer, to the effect that for an operation lasting from forty to sixty minutes the average quantity of the anæsthetic used was from six to eight ounces. His own experience in thirty cases had taught him that good results could be obtained with a smaller quantity—not more than two and one-half ounces in an operation lasting one hour.

Dr. Florian Krug, being unavoidably absent, sent a letter describing his experience with the new method. It was read by Dr. Meyer. He had employed the method in sixty-nine cases, most of them major operations. Solution No. 3 was employed, and the average duration of the anæsthesia was fifty minutes. The average time for the induction of anæsthesia was ten minutes. The average quantity of the solution used was seventy cubic centimetres, and the average quantity necessary for the entire period of anæsthesia one hundred and sixty-five cubic centimetres, or five and one-half ounces. In all but one of the cases the respiration and pulse were excellent. In four cases cyanosis was recorded. In no instance did it seem advisable to resort to any other anæsthetic.

Dr. Meyer, in closing the discussion, said that on corresponding with a number of wholesale chemists he had been astonished at the great difference of opinion existing among them regarding the properties of the petroleum ether, and particularly as to its boiling-point. It was not improbable that other anæsthetic mixtures would be discovered possessing the requisite maximum of evaporation, but the advantage of Schleich's solution was that only one new agent, petrolic ether, was introduced, the other components being familiar anæsthetics. Regarding the quantity used, the speaker said it depended very largely upon the kind of mask and the solution. The effect of solution No. 1 was much more transient than that of Nos. 2 and 3; hence for operations about the face one should always use No. 3. For such operations it would be difficult to keep the patient anæsthetized with No. 1.

Mode of Administration.—He believed that a mask which did not allow free evaporation was the best. As little as possible of the anæsthetic should be given: with the ordinary towel cone the quantity administered could not be estimated. Esmarch's mask covered with flannel and then with oil silk constituted the best arrangement, and it was convenient to have it provided with a funnel into which the anæsthetic agent could be dropped. The usual rule in administering chloroform was to give one drop about every five seconds: in the new method a drop should be allowed to fall on the mask about every second—in other words, it should be continuously dropped upon the mask. On an average he had used six or eight ounces of the anæsthetic for an operation lasting from forty-five minutes to two hours. The occasional cyanosis that had been observed did not seem to be fairly attributable to the anæsthetic itself. The respiration must be carefully watched, and if the breathing became rapid and deep the administration of the anæsthetic must be suspended and more air given. The whole narcosis was very similar to that of chloroform. The principal difference noticed so far was that, in from six hundred to one thousand administrations, in not a single instance had the patient been in a dangerous condition at any moment. In his own experience in only four per cent. of the cases had there been even slight albuminuria. Not a single death had been reported yet from the use of this anæsthetic.

Final Report of the Committee on the Abuse of Medical Charity—The Amended Dispensary Bill.—Dr. James Hawley Bürtenshaw, chairman, presented the final report of this committee. It had already received the endorsement of the several committees appointed with power to consider this matter. The bill provides that every dispensary, whether new or old, must be licensed by the State board of charities within six months after the passage of this act. This board has the power to issue the licenses, to make all the necessary rules and regulations for the government of dispensaries and other medical charities, and to revoke the license after satisfactory proof that the provisions of the act have been violated. Any person violating any of these provisions may be fined from $10 to $250. The act is to take effect immediately. It is claimed that this act will not interfere with any vested rights of corporations, and will not do injury to institutions properly and conscientiously conducted.

Dr. Landon Carter Gray said that it was an eminently just bill, and had met with the approbation of all the members of the medical community who could be interested in it. It had received the approval not only of the original committee of eleven, five of whom represented the colleges, but of the representatives from the other societies, and also of the comitia minora of this society.

The society accepted the report of the committee, and, in referring it to the committee on legislation, with power, instructed that committee to see that the bill be presented in Albany, and that it becomes a law as soon as possible.

Delegates to the State Society Instructed Regarding Dispensary Abuse.—Dr. Bürtenshaw then

offered the following resolutions, which were adopted unanimously:

"*Whereas*, The committee on abuse of medical charity, after thorough study of the question, has agreed upon the form of a legislative bill designed to correct existing dispensary abuses, which bill has been indorsed by this society and by nine other influential medical societies; and

"*Whereas*, It is desirable also to obtain for this bill the indorsement of the State Medical Society; therefore be it

"*Resolved*, That the delegates from this society to the State Medical Society be directed to attend the next meeting of the State Medical Society and present said bill to that society for indorsement; and that the delegates themselves be instructed to cast their votes in favor of such indorsement. And, as the annual election of officers of the State Medical Society occurs during the month of January next, be it

"*Resolved*, That the delegates from this society be instructed to vote at the election in favor only of those candidates who individually pledge themselves to indorse the passage of this bill by the legislature, and to vote against any and all candidates for office who may be opposed to said bill or to any similar bill or legislation."

Vote of Thanks.—On motion of Dr. F. R. Sturgis, the society tendered unanimously a vote of thanks to the committee, and the committee was discharged.

The Health Department and the Medical Profession.—The committee appointed to consider the relations of the health department and the medical profession reported that its time had been occupied chiefly with a consideration of the powers conferred upon the board of health and certain amendments that seemed advisable in the charter of Greater New York. It was evident that the powers now conferred on the health board are far beyond those originally intended, and are not necessary to secure proper sanitation. A portion of an official statement was quoted to prove that the board itself appreciated this fact. Among the more important proposed amendments are the following:

President of Health Board may be a Physician.—One amendment provides that the health board shall consist of the health officer of the port and four other persons, at least two of whom shall be physicians, and that a medical man may be elected to the presidency of this board if his colleagues see fit.

To Restrict the Jurisdiction of the Board.—The section defining the powers of the board it is proposed to alter, so that its jurisdiction shall be confined to matters of health only.

To Stop the Sale of Vaccine and Antitoxin.—It is also proposed to repeal the section which permits the board to sell vaccine lymph and diphtheria antitoxin if the supply shall exceed the amount required for the purposes of the department.

The report was accepted and its recommendations were adopted.

A Medical Commissioner of Charities.—On motion of Dr. Wickes Washburn, a resolution was adopted stating that it was the sense of the society that in the new commission of charities there should be a representative medical man.

Weak Heart.—1. There must never be less than five hours between one meal and another. 2. No solid food must ever be taken between meals. 3. All persons suffering from weak heart should take their principal meal in the middle of the day. 4. All those with weak hearts should take their meals as dry as possible.—Balfour.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 8, 1897.

Warren Coleman, M.D., Vice-President, in the Chair.

Echinococcus (?) Cyst of the Liver.—Dr. John H. Larkin presented a liver taken from a man, eighty-three years of age, who had enjoyed good health previously. There was no history of traumatism. In addition to the senile atrophy present in the liver, there was on the upper and posterior surface of the right lobe a large cyst, measuring five by three and three-fourth inches. The cyst wall was very dense and calcareous, and the contents were composed of gelatinous material, which on examination was found to consist of fat, with cholesterin and tyrosin crystals and fatty epithelium. The diaphragm was adherent and formed the upper portion of the cyst wall. The cyst contents were examined for ecchinococcus hooklets, but none was found. Nevertheless it was probable that this was a form of sterile ecchinococcus cyst of the liver.

Purulent Pericarditis: Operative Treatment.—Dr. Lewis A. Conner presented a specimen from a case of purulent pericarditis. The patient was a sailor, thirty-seven years of age, who had come under his care at the Hudson Street Hospital on March 9, 1897. The family history was negative. There was a moderate alcoholic habit, but he had had no serious previous illness. His last sickness began three days prior to admission, with sharp, lancinating pains in the chest, vomiting, and malaise, but without any chill. The next day there was a slight cough. On admission he complained of pain across the whole front of the chest; his temperature was 104.8 F.; respiration, 32; and pulse, 120. The physical examination showed some dulness at the right base posteriorly, over an area of three inches, with feeble breathing. On the left side, near the spine of the scapula, were dulness, prolonged high-pitched respiration, and exaggerated voice and whisper. Over both sides were many sibilant and sonorous râles. The area of cardiac dulness at that time was normal. The urine was normal, except for the presence of some red cells. For eleven days he presented the picture of a severe bronchopneumonia. There were a good deal of dyspnœa and cyanosis, and the cough was frequent. The sputum was examined several times without finding any tubercle bacilli. About ten days after admission his breathing improved, although his morning temperature was 101° F., and the evening temperature 105° F. He had had no chills. On the eleventh day the first sign of cardiac difficulty appeared. The cardiac sounds were decidedly fainter, and the impulse was less distinct. On March 22d the diagnosis of pericarditis with effusion could be positively made. The dyspnœa and cyanosis were then more marked. Two days later, his condition having become much worse, it was decided to aspirate. This was done in the fifth space on the left side, midway between the left border of the sternum and the nipple line. About nine hundred cubic centimetres of fairly thick offensive pus was evacuated. Within half an hour Dr. Stimson made an incision, under cocaine anæsthesia, over the site of the puncture, and removed about one inch of the cartilage of the fifth rib. What was at first supposed to be the pericardium proved on closer inspection to be a reduplication of the pleura. The pericardium was opened, and about two hundred cubic centimetres more of pus evacuated. The relief afforded by the operations was very striking. There was no evidence of shock after either operation. The patient's color and breathing were better for two or three days, but the temperature remained high. The wound was drained

with two large tubes, and irrigated daily. The discharge was quite free. Six days after operation the patient became delirious, and died on the eighth day after the operation.

The autopsy showed the pericardium adherent to the sternum and the pleura. It contained only a small quantity of pus. There was a small opening communicating with the left pleural cavity, which contained a sacculated empyema over the anterior surface of the left lung. This contained one hundred cubic centimetres of thick yellow pus, and had evidently been very imperfectly drained. The heart showed nothing abnormal in its interior. There were old adhesions over both lungs, but there was no evidence of any consolidation. The bronchi contained a good deal of muco-purulent secretion. There was moderate parenchymatous change in the kidneys. The original point of infection could not be discovered. Cultures showed a pure growth of the Fraenkel diplococcus.

Dr. Conner, in commenting on the case, said that the symptoms and physical signs had been those of a pulmonary lesion only. As these signs had improved, evidence of cardiac involvement had become evident. It was strange that the incision should have opened the pleural cavity. Dr. Roberts, of Philadelphia, had published, in the last number of the *American Journal of the Medical Sciences*, an exhaustive article on purulent pericarditis and the operative indications, giving a summary of about thirty-five reported cases that had been operated upon. Among these were a number in which the same accident had occurred as in the case just reported. It seemed evident that if the point selected for operation were outside of the internal mammary artery, yet well within the nipple line, there was always danger of infecting the pleura. A much safer site for the puncture was just to the left of the base of the xiphoid cartilage, between that and the free border of the ribs, the needle being passed obliquely upward. The chances of recovery seemed to be distinctly good if the accident mentioned were avoidable. Thus, of the thirty-five cases referred to, fifteen terminated in recovery, which was a very much better showing than from the non-operative treatment.

Fibrinous Hemorrhagic Perisplenitis.—Dr. Warren Coleman presented a spleen that was so adherent to the diaphragm that the latter had to be removed with it. The measurements of the spleen and attached diaphragm were seventeen by eleven by six centimetres, and the weight was one and three-fourths pounds. On making a longitudinal section through the organ, a moderately large amount of sanguineous liquid escaped from a cavity to be described later. It was found that the mass was made up in part of other than splenic tissue. The spleen itself measured fourteen by nine by three centimetres. Outside of the spleen and between it and the diaphragm was a moderately dense layer of new tissue, apparently a fibrinous deposit, which was divided approximately into two equal parts by a thin and more perfectly formed membrane. Between these two parts the cavity above referred to had formed. The adventitious layer measured three centimetres in its thickest portion. It covered the whole of the diaphragmatic surface of the spleen, and that surface only, thinning away somewhat as it reached the margins. From the pressure of the dividing layer it was assumed that the new tissue was deposited at two successive times. Cultures taken at the autopsy were negative, only putrefactive organisms being present. Sections of the new tissue show that it is composed of a meshwork of fibrin inclosing red blood cells. The capsule proper of the spleen has been invaded by small round cells, and the bundles of connective tissue have been separated from each other, giving a somewhat reticular appearance.

The patient was a woman, thirty-five years of age. The cause of death was lobar pneumonia. The heart weighed ten ounces; its walls were pale and soft. The mitral valve showed an increase of connective tissue along its free margin. The coronaries were normal. The left pleural cavity was partially obliterated, the result of an old pleurisy; the right was wholly obliterated from the same cause, and the costal pleura was much thickened. The bronchial glands were enlarged, pigmented, and tuberculous. There was pneumonic consolidation of the whole of the right lung, the process having commenced in the middle lobe and upper part of the lower, and then extended. A little blood was present in the pelvic cavity, but was believed to have come from the omentum. The kidneys presented the changes of extensive parenchymatous degeneration, with a moderate connective-tissue increase in places. Each kidney had two ureters, which united a short distance above the bladder.

Aneurismal Dilatation of the Pulmonary Valve.—Dr. Coleman also presented a specimen showing aneurismal dilatation of the pulmonary valve. It was taken from a woman, about fifty years of age, who was found dead. The cause of death was general pulmonary tuberculosis, which had originated in an old process at the left apex, where a small cavity had formed. Miliary tubercles were scattered throughout the rest of both lungs. The lungs were likewise emphysematous. There was no lesion in the pulmonary arteries macroscopically demonstrable. The heart had stopped in diastole, and both sides were filled with dark coagula. All three cusps of the pulmonary valve presented the changes of chronic fibroid endocarditis, especially marked in the left anterior cusp, which was the seat of the dilatation. Here the connective-tissue increase was most pronounced. The dilatation was greatest about the middle of the cusp, below the corpus Arantii. The cusp at this point projected about three millimetres farther into the lumen of the arterial ring than normal. The right ventricle was distinctly hypertrophied and dilated. The only discoverable lesion which could have tended to produce the changes in the valves was emphysema, with its vascular changes. The tuberculous process at the apex was not sufficiently extensive or sufficiently fibroid to have raised the blood pressure in the pulmonary circuit to any extent. As already stated, there were no atheromatous changes in the larger divisions of the pulmonary artery. The changes in the smaller branches of the pulmonary artery, however, must have been more extensive than was ordinary in emphysema. Emphysema, with right-heart hypertrophy, is comparatively common; changes in the pulmonary valve are very rare. The nature of the lesion in the valve was such that it could not have given origin to any symptoms or signs during life. Affections of the pulmonary valve are very rare, and usually congenital. The valve had been the seat, however, in adults, of simple, acute, and malignant endocarditis.

Dr. J. G. Adami, of Montreal, asked, in regard to Dr. Coleman's case of perisplenitis, if there had been any disturbance in the spleen itself, or if the disturbance had been sharply defined from the spleen substance.

Dr. Coleman replied by exhibiting specimens under the microscope. They showed nothing abnormal in the splenic tissue.

Dr. Adami said that the nearest approach to such a condition that he had met with was in a case of fibroid pneumonia with bad resolution. The post-mortem showed the left lung to be firmly adherent to the diaphragm, and in one portion a small gangrenous area. The spleen was separated from the diaphragm by a thick mass similar to that described in Dr. Coleman's case, and in the middle of this mass there was

definite suppuration. Along the splenic vein, near the pancreas, was another small abscess, and there were also multiple abscesses in the liver. It seemed to him that there must have been a microbic infection from the lung to the perisplenic tissue, setting up suppuration, and thence through the splenic vein to the liver.

Dr. Coleman said that in his case the pneumonia was on the right side, and there was no lesion found except an enlargement of the spleen, which was soft and dark. There was an old interstitial pleurisy, which did not entirely obliterate the cavity.

Subglottic Abscess—Death from Œdema of the Glottis.—Dr. James Ewing presented a larynx taken from a case of subglottic abscess, which had had a rather sudden and fatal termination from general œdema of the glottis. The history was very imperfect, and was obtained only from the family. The patient had been taken sick with the ordinary symptoms of cold, four days before admission to the hospital. He suffered from pains in the joints, but principally from a sore throat and slight cough, with scanty mucoid expectoration. He was not considered seriously ill at first. Examination showed considerable swelling around the base of the epiglottis, but not much obstruction of the rima glottidis, in spite of the presence of considerable dyspnœa. Shortly after admission the dyspnœa increased rather suddenly, and became markedly stridulous. Operative interference of any kind was declined. He suddenly became unconscious, and a hurried tracheotomy was performed, but it did not save him.

At the post-mortem examination there was nothing of special interest in the body, such as tuberculosis or syphilis. There were the ordinary post-mortem findings of previously existing and severe general œdema of the epiglottis and of the whole of the larynx. The mucous membrane of the vocal cords was white and thick, and, being very anæmic, resembled somewhat a false membrane. On careful examination, behind and below the posterior attachment of the right vocal cord, a small opening was found in the mucous membrane, which communicated with a small abscess cavity containing creamy pus. On section an abscess cavity, measuring about one centimetre in diameter, was found, which was lined with the ordinary pyogenic membrane. This was the only inflammatory lesion of importance in this region. Cultures made from the pus showed no Klebs-Loeffler or tubercle bacilli, and sections of the wall of the abscess cavity showed ordinary granulation tissue. There was no history or other evidence of syphilis or tuberculosis; hence the case seemed to be one of simple primary abscess, arising probably from the larynx. The object in presenting the case was to place on record a rather rare termination of laryngitis.

Filaria Sanguinis Stained.—Dr. Ewing exhibited under the microscope a slide showing the filaria sanguinis. He said that he was indebted to the authorities of the New York Hospital, and especially to the house physician, for the specimen. An interesting feature in it was the very satisfactory staining. The smears were made in the ordinary way, fixed in alcohol and ether, and stained with methylene blue. The structure of the filaria was in this way very beautifully brought out. The granular structure of the body was thus made evident, and when examined dry, without any mounting-medium, the envelope of the filaria could be plainly seen. This disappeared when the specimen was mounted in a medium having a higher refractive index than air. He had searched very carefully, but in vain, for the cilia described by some writers as attached to the sheath of the filaria. The method of preparation just described was a good way of preserving such a specimen permanently.

In answer to a question from Dr. Adami, Dr. Ewing said that the specimen presented was certainly much larger than the filaria most commonly seen.

Dr. Adami said that, as there was reason to believe that there is a new species of filaria in the West Indies, all cases of the kind coming from there should be very carefully examined.

Tuberculous Disease of the Vertebræ.—Dr. V. P. Gibney presented a specimen showing tuberculous disease of the vertebræ. It had been removed from a boy, who was ten years of age when admitted to the hospital on July 16, 1895. He had been suffering from spinal disease for a long time previously. Examination showed a moderate kyphosis in the lower dorsal and first lumbar vertebræ. Shortly before his admission a psoas abscess had developed on the right side. This was tapped, but the fluid was too thick to pass through a large needle. About a month later the abscess was opened, and from four to six ounces of thick, caseous pus was removed. A month after this the opening was enlarged and the curette passed upward into the lumbar vertebræ, and bits of bone were removed from the vertebræ. The sinus remained open from that time on, and the case steadily grew worse. It was reported as an example of the failure of excellent hygienic surroundings to induce a good reparative process. In the summer of 1896 this boy had spent four or five months continuously in an excellent summer hospital at Englewood, where he had had every advantage. A few months later he had been sent to the country for the winter. His back was well protected by a jacket, he was outdoors a good deal, and had the best of air and nourishment. Last summer he was also in the country. In spite of these advantages, the sinus steadily discharged and the liver began to enlarge. Last summer he presented symptoms of what was considered by some of the consulting staff to be pulmonary tuberculosis. The child died on December 6th, and the autopsy was made by Dr. Buxton. On section of the spinal column comparatively a small area of disease was found, with only a few loose pieces of bone. The lungs were absolutely normal, except for general atelectasis resulting from pressure of the diaphragm and the enormously enlarged liver. The brain was not examined. The heart was normal. The pericardium contained about four ounces of fluid. The pleura was slightly adherent; its external surface was smooth; there were no tubercles. The bronchial glands were enlarged and calcareous. The abdomen contained six or eight ounces of fluid. The spleen was enlarged and pale. The kidneys were the seat of an acute parenchymatous nephritis and some amyloid change. The intestine was normal. The mesenteric and retroperitoneal glands were enlarged and caseous. The liver weighed six pounds, and was smooth and hard.

The society then adjourned.

In Psoriasis cacodylic acid has been advocated by Daulas (*Therap. Wochens.*, No. 22, 1897). The following formula is given:

℞ Acid. cacodylic	5
Rum	40
Syr. aurant. cort	40
Aq. dest.	120
Ol. menth. pip.	q.s.

M. S. Six teaspoonfuls daily.

Among the disadvantages which have been noted are a garlic-like odor of breath, occasional slight gastric disturbances, and, as recently pointed out by Balzer and Griffon, an erythroderma with extensive desquamation resembling that of scarlatina may occur after the dose of eight grains daily is reached. Eczema has also been produced.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CENTRAL HOSPITAL BOARD—HOSPITAL ABUSE, NEWPORT INFIRMARY DISPUTE—UNPLEASANT APPEARANCES IN THE NEWSPAPERS—ACTION FOR NEGLIGENCE AND A SECRET POST-MORTEM — EPIDEMICS — PANCREATIC CYSTS—BRITISH MEDICAL PLEBISCITE—ADELAIDE UNIVERSITY AND SCHOOL'S FORTUNE—SIR CH. NICHOLSON, BART.—LONDON UNIVERSITY SCHEMES.

London, December 17, 1897.

Another meeting got up by the Charity Organization Society in favor of a Central Hospital board was held on Monday. Sir W. Broadbent moved a resolution expressing the great importance of the scheme. He disclaimed all hostility to hospitals, as he might perhaps well do in addressing the public, but would scarcely consider it necessary if speaking to the profession. He also said there was no intention to adopt coercive measures toward any boards that did not fall in with the organization's views, but he hoped it would have a voice in the disposal of the Prince of Wales' fund.

Sir Joseph Fayrer, Mr. Victor Horsley, and Dr. Glover also gave a general support to the scheme. Other gentlemen, however, took grave objection and pointed out some of the dangers ahead. Among these were the great power of the purse if the proposed board had large funds to allocate; the impossibility of a board of two hundred persons carrying on the business part, and therefore the certainty that the control would fall into the hands of a few zealous but probably prejudiced persons. This has happened with the Sunday fund. It is significant that the managers of hospitals were practically unrepresented at the meeting. They doubtless see difficulties in the way, and are not disposed to give up their authority to a board of which it is impossible to foresee the action or predicate its fitness for the work.

A lurid light is shed on hospital abuse and the difficulty of controlling it, by what promises to become another scandal. At Newport, Monmouth, the directors of the infirmary have taken the high-handed measure of dismissing one of the staff because he declined to treat patients who were not proper objects of charity. Two cases were refused after the directors had taken no notice of others which had been referred to them for inquiry. The families were earning £117 and £153 respectively. The ophthalmic surgeon, Dr. Ensor, declined to treat them, in the hope that his action would lead to a wage limit or the appointment of an inquiry officer. The works where the patients were employed subscribe £10 10*s.* per annum, and the men collect about £60. The directors seem to fear the loss of these sums. The workpeople seem to fancy their collections give them a right to free hospital treatment, thus putting the charity on a par with clubs. Complications of this kind are likely to occur elsewhere, and subscribers and others must be educated on the subject. The Cardiff Medical Society has taken up the subject and unanimously passed a resolution, expressing the hope that the board will see its way to withdraw the notice it has given to Dr. Ensor. This would be the best thing to do. It would clear the way for a temperate discussion of the difficulties by all concerned, and surely some rules might be framed which would give satisfaction to the staff as well as to the managers. The latter no doubt have the real interests of the charity at heart, and should not be blind to the injury that would result from injustice to the staff.

Quite a run of unpleasant cases have been reported in the newspapers. One promising young doctor, suffering from insomnia, resorted to chloral hydrate, and eventually took an overdose. Verdict, accidental death. A more depressing case is a "suicide during temporary insanity," apparently caused by a serious charge having been made against the victim. A practitioner of many years' standing sold his practice, and the purchaser has just sued him for misrepresentation. An attempt to levy blackmail was defeated by the doctor promptly handing the criminal over to the police —certainly the most sensible course to adopt. Other similar cases have occurred, and the divorce court has also had cases of practitioners to investigate.

In an action against a doctor for negligence, the plaintiff is said to have been attended gratuitously, and the doctor even called in a consultant and paid the fee himself. Of course the poor man's proceeding is got up by a lawyer. All that is to be taken for granted, gratitude being unknown to gratis patients of a sort. But what demands the notice of the medical council is that a neighboring practitioner and his partner with one of the staff of the Westminster Hospital made a post-mortem behind the back of the accused. In court two of these persons gave evidence on the strength of this secret post-mortem, against the diagnosis and treatment of the accused doctor. Their "expert evidence" seems to be as shaky as their ethical conduct, which should attract the attention of the licensing authorities concerned, of the Medical Council, and of the other members of the staff of the Westminster Hospital.

The decline of the typhoid epidemics is restoring hope if not confidence in the towns affected. At Maidstone the mortality has been light, averaging under eight per cent., the total deaths being one hundred and forty-three out of eighteen hundred and eighty-six cases. The emergency hospitals are being closed, and many nurses dispensed with. At King's Lynn there were ten fresh cases last week, bringing the total to four hundred and thirty-five.

The discussion on typhoid prevention by the Medico-Chirurgical Society has again been adjourned, so I will postpone remarks upon it.

A severe epidemic of measles has occurred at Barking. It is said that above one thousand cases have occurred; but measles is not a notifiable disease, so the figures may not be correct. About thirty deaths have beeu registered. The schools in the town and neighborhood have been closed.

Pancreatic cysts occupied the attention of the Medical Society on Monday evening. Mr. Doran gave an account of a case in which a cyst was attached by a broad base to the body of the pancreas. He sutured the cyst to the abdominal wall and inserted a drainage tube. Forty-four ounces of yellow fluid escaped and a fistula remained open from May to October. The patient was a single woman, aged twenty-four years, and Mr. Doran remarked that these cysts may form at any age. He considers total removal justifiable, even if the tail of the pancreas be included, provided a pedicle can be formed, but removal of a sessile cyst is not to be attempted. The results of drainage are, he thought, fairly satisfactory, and there is great danger in aspirating or tapping for diagnostic purposes.

Dr. Rolleston and Mr. Turner related a case in a man of thirty years. A tumor below the liver was diagnosed as distended gall bladder, but proved on operation to be a cyst arising near the pancreas: it was not possible to be more precise than to call it peripancreatic. About thirty ounces of dark fluid which yielded no ferments was removed by tapping, and a good recovery followed.

Mr. Malcolm related a case of supposed hydronephrosis which proved to be a multilocular cyst contain-

ing a fluid with amylolytic reaction. It arose in the tail and the hemorrhage was very difficult to arrest. Another case was mentioned, in which Mr. Gould operated, the only symptom in which at first was jaundice; subsequently a tumor formed. Mr. Battle mentioned yet another case in which he cut down upon an undetermined swelling, but its appearance was so malignant he left it alone. Nevertheless the patient made a good recovery, and Mr. Battle did not pretend to know what the tumor was.

The *plebiscite* agreed to be taken of the British Medical Association, as to whether it should undertake medical defence, is now in progress. Reply postcards have been issued with a request that they be returned immediately. The colonial branches are also to be consulted, so the returns cannot be complete for some time.

The University of Adelaide benefits to the extent of £25,000 and the Medical School by a further £20,000 under the will of the late Sir T. Elder.

Sir Ch. Nicholson, Bart., is best known as a colonial politician. He was the first president of the Queensland legislative council, and presided over three earlier Australian assemblies. He is, however, a doctor—M.D., LL.D., D.C.L. He was chancellor of Sydney University. He is now a nonagenarian and living near London.

The London University question is receiving the attention of the newspapers, in the anticipation that the government will this year introduce a measure early enough to give it a chance of passing. The senate of the existing university met the representatives of about twenty educational bodies on Tuesday, under the presidency of Lord Herschell, who urged that all parties should be prepared to accept some compromise. A deputation is expected to wait on the president of the council, in which the senate, the convocation, the two royal colleges, the corporation of London, and other bodies will be represented. The medical schools are almost equally divided as to the schemes they would like. They must take Lord Herschel's advice and be prepared for a compromise. Otherwise the government may force on them something they do not want, or, if opposition is offered, may again postpone action.

STATISTICS OF ABDOMINAL SECTION IN AMERICA.

To the Editor of the Medical Record.

Sir: I have just had sent to me a copy of the forty-first annual report of the Hospital for Women in New York, containing an address by Dr. T. Gaillard Thomas, the greater part of which purports to answer some animadversions which are alleged to have been made concerning the results of the work in that institution. At the conclusion he puts to the critics Shylock's question, "Are you answered?"

I have not been one of the critics, and only because the facts never came under my notice; but on their behalf, and on behalf of suffering humanity, I say to Dr. Thomas that they are not answered, but that on the contrary he makes out a most deplorable state of matters.

He puts forward a group of figures which shows that in seven large selected hospitals in America the results in abdominal section run from 25 per cent. in Boston City Hospital down to 15.03 per cent. in his own institution. Of this collection of statistics I have only two things to say—that the whole thing is deplorable and must be remedied; and that the mortality in the New York Woman's Hospital is "murderous," as Mathews Duncan used to put it.

He certainly does not make the matter any better by pointing out that during a period of thirteen years the mortality of his hospital has been 22.43 per cent., and that this triumphant result has been due to the introduction of "antisepsis, the sheet anchor of the surgeon." This makes me more than ever thankful that I discovered early in my career the fallacy of this so-called antiseptic craze.

I inclose with this letter a copy of the twenty-third annual report of the Birmingham and Midland Hospital for Women, for 1893; and I select this year for three reasons. The first is that it was the first year in which no work was done by myself and the bulk of it was done by two of my former assistants, and because it was an exceptionally bad year.

As to the statistics themselves, let me say that, like those of the New York Hospital for Women, in Dr. Thomas' own words: "The surgical staff of this hospital has absolutely nothing to do with the making of its statistics." Each case is entered by an officer responsible to the lay committee, and each fatal case is investigated by a special pathologist altogether independent of the operating staff. At the end of each year each operator has to defend his facts before his colleagues on a committee upon which also sit the chairman and secretary of the managing committee, and a perfect audit is made and signed. This document is published with a table upon which every case is entered under the distinguishing initial of its own surgeon, and with such details that any case can be easily identified. Any cooking of the statistics is an absolute impossibility, and only the most trivial errors have been ever detected.

In 1893 the abdominal sections numbered 176 (against 153 in New York in 1894), with a mortality of 6.2 against 15.03 per cent. in the New York Woman's Hospital.

Another table is given of 1,350 cases of abdominal section, performed almost entirely by Dr. Savage and myself, from 1884 to 1893, with 75 deaths—a mortality of 5.5 per cent.

During these years I did all my work on plain soap and water, having abandoned every trace of the varying absurdities of Listerism two years before. Dr. Savage followed Lister in fashion of his own, varying from time to time. The work was fairly well divided between us, as also was the mortality, and with the most careful reckoning of the figures the verdict against Listerism must be, in Scotch fashion, "Not proven;" for with its complete absence my results were no worse, and with its partial presence Dr. Savage did no better.

What can Dr. Thomas have to say to this?

I have only to say that his results show that there is something radically wrong with his hospital, and that the medical profession of America, advancing as it is beyond the progress of our art in all other countries, cannot afford to let matters go on as they are.

If I may answer in one word the question which will of course follow what I have said—What is the cause of your success?—I say emphatically, the absolute segregation of our patients and close attention to every detail constitute the whole of the mystery.

That there is an inevitable mortality in abdominal section I think is certain. That two men, working in the same place, with the same material, should bring it down during ten years to 5.5 per cent. in a continuous, consecutive series of 1,350 cases, shows that the inevitable mortality is pretty nearly reached. That a removable mortality of more than three times that amount should be allowed to remain as the minimum to be reached in America cannot be admitted for a moment.

That even the low mortality we have had in Birmingham is probably not the inevitable mortality is, I

think, almost proved by a little figure twisting; for if we take out four bad years—1884, 1889, 1890, 1893—we find 553 cases, with a mortality of 8.5 per cent. But in six good years—1885, 1886, 1887, 1888, 1891, 1892—we had 797 cases, with a mortality of 3.5 per cent. I think this latter is nearer the inevitable, and that a higher mortality than that is due to causes entirely removable. All such causes ought to be earnestly sought for and removed at any cost.

LAWSON TAIT.

BIRMINGHAM, ENG., December 14, 1897.

"SHOULD MINISTERS PAY DOCTORS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am interested in as well as amused by the recent articles in the MEDICAL RECORD on this practical subject. Having had some experience along this line, I can relate some interesting episodes, while I reserve the right and pleasure of treating my own pastors (who have always treated me generously) gratuitously so far as commercial matters go.

I think I can "go" Dr. Lynch "one better" on the pineapple deal. Many years ago I treated and nursed the spiritual adviser of a neighboring church society through many weary weeks of suffering and illness resulting from a fractured thigh. Considerable expense to myself was attached to the case. Upon getting about again he asked me for my bill, and I replied that I had made no account against him but had "charged the account to the Lord." He thanked me warmly and expressed very great gratitude. Some months afterward my marriage occurred, and this reverend gentleman and his wife were guests at the wedding. They felt that they must show their gratitude to us in some way, and so, nicely rolled up in the finest quality of tissue paper, came an enormous engraving, a cheap woodcut of "The Three Graces," to frame which would have cost me at least $4 or $5. Now, I dare say Dr. Lynch would rather have the pineapple. The engraving had been obtained as a premium for subscribers to a religious paper.

This reverend gentleman's successor also employed me to a large extent and at considerable expense to myself, and upon his retirement from the field was very grateful to me, so much so that during the following summer he made a house-to-house canvas among his old parishioners, and urged them to employ a certain newly arrived doctor who belonged to his particular church.

I can assure you, Mr. Editor, that that class of men has since been made to know something of my own estimation of the value of my services.

J. R. STURTEVANT, M.D.

THERESA, N. Y., December 27, 1897.

SUGGESTIONS FROM READING THE LAST "MEDICAL RECORD."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Every number of the MEDICAL RECORD suggests thoughts and I have frequently been inclined to send you for publication those which occur to me. If your readers generally would do this, much practical information would be disseminated and the profession would faster advance toward the *ultima thule* of medicine, viz., the cure of disease. We seem to know everything else in medicine except this. We have many fine surgeons, but few medicinal remedies.

No. 1.—Is not the creosote treatment of tuberculosis about "played out"? It has certainly had its day, because no good seems to come of it. Turpentine in emulsion is just as good, if not better, and is far less disagreeable to take and much better tolerated by the stomach. It should always be administered on an empty stomach and at least one hour before taking food. It is an antiseptic of power, and stimulates the general glandular system, especially the mesenteric glands. I greatly prefer it to creosote, and usually administer it in the following formula:

R Olei terebinth. ..... ℥ ss.
Cretæ prep. et
Sach. alb. ..... āā ℥ ij.
Pulv. acac. et
Aquæ cin. ..... āā q.s. emul. ℥ iv.

S. Dessertspoonful three times a day upon an empty stomach ("shake" label).

From articles heretofore published in the MEDICAL RECORD your readers already know that I believe the disease to be one of malnutrition, originating in the blood-making organs, and that the pulmonary and other symptoms are secondary, with the bacilli following and not preceding the lesions. The primary indication, then, is to aid the system in making a full supply of normal blood, and in accomplishing this the cure is wrought. Whatever promotes this is beneficial, and whatever retards this is injurious and harmful.

The best general medical treatment that I have ever employed in the disease is the turpentine mixture as indicated above, with whiskey saturated with Turk Island salt, one hour after each meal. I usually put one-half pound of the salt crystals in a quart of whiskey, so that the liquor is supersaturated, many of the crystals remaining undissolved. The dose is regulated according to the weight, age, habits, and condition of the patient, always diluted with water. This seems to promote digestion, assimilation, and all the blood-making functions, and at the same time it retards tissue waste. Of course all other hygienic measures should be applied, and unusual symptoms should receive attention as they arise. It may also be necessary to withhold the turpentine for a few days at a time, either from its effect upon the vascular system in drying the mucous membranes or its action upon the urinary tract. A number of incipient cases have been cured by this treatment in my hands, and the only objection I have found to using it is that many patients will not discontinue the treatment at my bidding. It seems to them so beneficial that they cannot survive without it.

No. 2.—On page 903 you give from Holton the following formula:

R Tr. lobeliæ. ..... gtt. i.
Aquæ. ..... ℥ i.

M. To be used in one-drop doses for colic in infants.

I have reared ten children of my own, and many more of those of my patients, on the following:

VINUM LOBELIÆ COMP.

R Pulv. lobeliæ fol ..... ℥ ij.
Pulv. cypripedium et
Pulv. ictodes ..... āā ℥ i.
Pulv. menth. pip. et
Pulv. anisi sem. ..... āā ℥ ss.
Vin. xericum ..... ♁ ij.

M. Agitate daily for two weeks and filter.

This makes an elegant and agreeable preparation, and it is excellent not only for colic but for every acute inflammatory condition—coughs, cold, fevers, etc. It can do no harm, as the worst it can accomplish is to effect emesis, and when given to this extent will relieve all of these forms of disease. The depressant effect of the lobelia is so fully counteracted by the menstruum that no injurious relaxation can occur. It should be administered in hot water, sweetened, four parts to one of the medicine; or for very young infants—a day old, for instance—it may be diluted even more. It promotes sleep, and has been used exten-

sively in my practice with children in place of paregoric. I have yet to see a single alarming symptom arising from its use.

In the first stages of pneumonia it is the remedy *par excellence*. In tablespoonful doses for an adult in a gill of hot water every hour until it effects free diaphoresis, and if necessary pushed to emesis, it will relieve the congestion and cure the disease. If there is a cure, this is the remedy, a hundred times safer than veratrum and a thousand times safer than aconite.

No. 3.—On page 890 you have the "twenty-five-cent doctor." The country is full of them. With proprietary preparations, tablets, and triturates, they go from house to house and furnish the medicines, or poisons, all for twenty-five cents; while if the patient calls upon a reputable physician he must pay him a dollar and then go to the druggist and pay another dollar. In an agricultural community, where money is gained by hard work and not much obtained by that, the twenty-five-cent doctor is always the busy practitioner; while the more reputable doctor is called upon only by the few, or by the "twenty-five-cent doctor" himself when he gets into a surgical or obstetrical scrape.

MILFORD, DEL., December 22, 1897.

New Instruments.

A NEW AND SIMPLE BATH FOR FEVER PATIENTS.

BY ALFRED COLES HAVEN, M.D.,

LAKE FOREST, ILL.

CULLEN, a century ago, advocated the cold bath in fevers. Brand more recently has developed and proved its usefulness. To-day the cold bath is acknowledged as the most perfect method of combating fever. In typhoid, where its benefit is most striking, it reduces fever, modifying the general course of the disease; favors elimination of the poisonous ptomains, the pathogenic factors; besides strengthening the heart, stimulating respiration, quieting nervous excitement, producing profuse diuresis, keeping the skin soft and healthy, lessening tendency to bedsores; and generally it is followed by a grateful and refreshing sleep. I have seen a bath of 90° F. reduce the patient's fever three degrees; again, one of 70° F. produced no reduction whatever. These are both exceptional cases, at the two extremes. I do not condemn the bath when the fever is not reduced, for elimination and the other favorable features are still preserved. Ordinarily I begin a bath with a temperature of 90° F., and reduce it to 75° or 70° F., meanwhile using vigorous frictions with a piece of Turkish towelling all over the body and limbs, except the abdomen in typhoid. Ten or fifteen minutes usually suffices.

Why is such a useful therapeutic remedy not universally recognized and used? The people, and too often the profession, do not appreciate with what ease and simplicity the bath can be given. They argue: "The bath is all right for the hospital, but would never do for general use in private practice. It requires too many assistants, people are prejudiced against it, and often no tub is at hand and the expense of buying one is considerable."

The Furbush bath, made in Philadelphia, and the Burr bath of Chicago, meet these indications to a certain extent. They are portable, and both enable the patient to be bathed in bed. But, first, they are expensive, placing them beyond the reach of the masses: second, they both have clumsy frameworks of wood that render them difficult to transport by hand: third, the patient, if unaccustomed to bathe, is often alarmed by the extensive paraphernalia, especially the framework of the Burr bath, which is lifted over the patient.

I have used the Burr bath with great satisfaction, but, appreciating its defects, have sought to devise a much simpler bath, which would be equally serviceable, with some important additions. In the first place, I have done away entirely with the cumbersome framework; then I have reduced its cost to an insignificant sum, placing it within the reach of all. It can be manipulated with far less effort. The siphon has a plug, which allows of deliberation in its use in emptying the bath, and the whole structure can be rolled into a little package no larger than a small travelling bag. I append a description: Two leather straps, five feet long, one inch wide, each with an ordinary buckle in the centre; at either end of each strap is a hook, and two small rings sewed near the centre of each strap, two feet apart, serve to receive snaps on the end of two parallel ropes, which map out the framework of the bath. The ropes are passed through hems in a rubber sheet, three yards long and one and one-fourth yards wide. The straps are attached, one to the headboard and the other to the footboard of the bed. To empty the bath, one side of the tub is let down by unfastening a snap and a valley made of the rubber cloth guides the water into a tub on the floor, finishing with the siphon.

A still cheaper form of bath may be improvised out of a clothesline, a dozen ordinary wooden clothespins, and three yards of table oilcloth. Tie a loop of rope firmly around the headboard, another around the footboard, and connect by two parallel ropes. Attach oilcloth with clothespins, and you have as comfortable a bath as the most expensive, at a cost not exceeding seventy-five cents. The loops around the headboard and footboard may be dispensed with in metal beds. Four feet of garden hose with a wooden plug in one end makes an excellent siphon. Such a bath I have now in use.

I believe I have simplified the bath so that it is within the reach of all. The materials for the simpler form can be obtained at any country grocery store; and the more elaborate one which I have described can be sold at less than half the usual price of such luxuries, and I believe it is far simpler and equally efficient.

My only desire is to extend the benefits of the bath to the masses. The patient in the crowded tenement and in the country farmhouse can be shown by his physician in a moment how to obtain the benefits of that health-giving fluid—cold water.

AN AUTOMATIC LIGATURE PASSER.

BY E. PURRE MALLETT, M.D.,

NEW YORK,

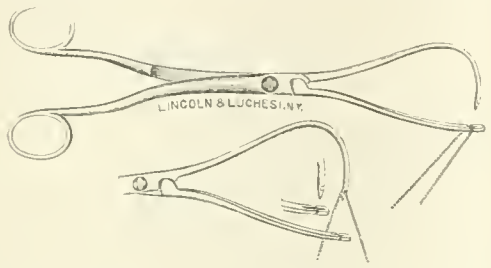
ASSISTANT GYNÆCOLOGIST, COLUMBUS HOSPITAL, VANDERBILT CLINIC, ETC.

THERE seems to be such a multiplicity of new instruments and modifications of old ones constantly appearing that one hesitates to suggest another. Still the most enthusiastic and advanced surgeon would hardly care to say that his methods and appliances had as yet reached perfection, so that any instrument claiming to simplify and expedite the graver operations will at least be regarded with interest by progressive men.

The instrument shown in the accompanying cut I have devised to facilitate the tying-off of pedicles and the ligation of vessels in the most inaccessible parts of the abdominal cavity. As its principle is entirely different from that of any other instrument with which I am familiar, a somewhat detailed description is necessary. It is composed of two blades—the upper or penetrating blade being fashioned like an aneurism

needle, with an open or self-threading eye. The lower blade is blunt and smooth, and acts as a counterpressure to the needle. In the end of this lower blade is a small slot just large enough to admit the needle, and across this slot is a groove which receives and retains the ligature until picked up by the needle. That comprises the entire mechanism.

The *modus operandi* is simplicity itself, and is as follows: The instrument is opened, thus separating the blades. A ligature of the desired size is then firmly placed in the groove of the lower blade. To pass the ligature this blade, the lower one, is introduced behind the pedicle or structure to be ligated (generally guided by the fingers of the left hand, which is grasping the pedicle), while the needle blade is passing at the same time over the upper surface of the pedicle, under guidance of the eye. When that part of the pedicle is reached where it is desired to pass the ligature, the instrument is simply closed and rapidly opened again and withdrawn, the ligature appearing in the eye of



the needle blade, having been caught automatically from the groove of the lower blade by the open eye of the upper blade and pulled through the tissue.

The upper figure in the cut shows the ligature in position upon the lower blade, with the needle blade ready to transfix the pedicle when compression is made upon the scissor handles; while the lower figure shows the needle blade having transfixed the pedicle and carried the ligature through with it.

The advantages this instrument would seem to possess over those in use at the present time for similar purposes are:

First, the ease, accuracy, and rapidity by which ligatures can be passed through any tissues, particularly those situated deeply in the pelvis.

Second, ligatures can be passed with the structures *in situ*, the advantages of which are obvious.

Third, the operator is not dependent upon the skill or dexterity of an assistant in either catching the ligature when it has been passed through the tissues by the pedicle needle, or in placing the ligature within the grasp of the Cleveland passer, if that instrument is used; but the operator is thus enabled to pass the ligature entirely with his right hand, while his left hand maintains the structures in proper position.

The mechanical details have been successfully carried out for me by Messrs. Lincoln & Luchesi.

65 West Sixty-Ninth Street.

The South and Yellow Fever.—The numerous conflicting and in many instances ridiculous quarantine regulations formulated by State, county, and municipal authorities, and enforced oftentimes by excited and inexperienced men, aided in some cases by the shotgun, during the epidemic of yellow fever which has just prevailed in the Gulf States; the utter disregard of commercial and railway interests, and in the end the complete failure to arrest the passage of the contagion from town to town and State to State, form a telling object lesson, which must convince the stanchest supporter of State autonomy that the Federal government should take entire and complete control of quarantine in such diseases.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 1, 1898:

	Cases.	Deaths.
Tuberculosis	136	106
Typhoid fever	17	8
Scarlet fever	193	20
Measles	267	8
Diphtheria	167	19
Laryngeal diphtheria (croup)	2	1
Chicken-pox	19	0
Cerebro-spinal meningitis	0	1

The Number of Physicians in Germany and England.—According to the Borner Reichsmedicinal-Kalender for 1897, there were in Germany, in November, 1896, 24,000 physicians, and this number showed an increase of 901 over the previous year. Great Britain had, in 1897, 34,284 physicians, and this showed an increase of 988 over the preceding year. In London there was 1 doctor to every 850 inhabitants, while outside of this city there was 1 doctor to 1,700 inhabitants.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CLINICAL OBSERVATIONS ON MALARIA AND ITS TREATMENT.[1]

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

THE usual intermittent form of malarial fever as we meet with it in New York practice, both in and out of hospital wards, is as a rule readily diagnosed. Not that errors even in these cases do not occur, because as a fact they do. Despite our most careful estimate of a given case, I have known more than once a so-called example of intermittent fever ultimately to be determined to be one of gall stones, tuberculosis, or typhoid fever. Still when the liver and gall bladder are carefully considered, the expectoration is microscopically examined, and the blood or serum investigated as to characteristic clumping, such mistakes are relatively infrequent. On the other hand, if we rely solely upon the discovery of the malarial parasite even in these cases to fix our diagnosis, we shall not infrequently remain in legitimate doubt about the nature of the case we are treating.

I have an example present to my mind of a young woman in my ward at St. Luke's Hospital, with the history of malarial fever taken at the Isthmus of Panama, who had a succession of chills followed by fever and sweating. Yet no malarial organism was ever detected in her blood, though several careful examinations were made during or just subsequent to the period of chill. Again, in this case quinine, Warburg's tincture, and nitrate of potassium were taken without curative effect, and arsenic in frequent increasing doses alone proved effectual. Not only this, but the spleen even during the paroxysm of fever was neither tender nor enlarged. And here I feel constrained to say that, valuable as I have found microscopical examinations in many of these cases of intermittent fever to determine the differential diagnosis, still Laveran's great discovery must not be regarded as final in all such cases, because at times it will unquestionably prove to be unsatisfactory. Of course I recognize that the search for the malarial organism must be made skilfully, patiently, and with suitable instrument and at proper time. Nevertheless, there are cases in which the malarial parasite cannot be found. The cases, however, which give most trouble, remain most uncertain, and are never settled definitely except by the touchstone of treatment, are those cases of continuous fever which last many days, and even weeks, and finally are designated, properly as I believe, malarial, because no other satisfactory diagnosis can be made. They are not cases of typhoid fever, because their temperature charts never show the rises and falls which are characteristic of typhoid fever. They have no lenticular eruption, no bronchitis, no diarrhœa, no tenderness in the right iliac fossa, no clumping of the red globules with the application of Widal's culture test. They are not tuberculous, because no bacilli are found, no pulmonary or peritoneal symptoms sooner or later point to it. They are not hepatic in origin, because there are no biliary colics, no distention of the gall bladder, no jaundice, and the age and previous history practically eliminate this diagnosis. Shall we name cases of fever prolonged for a week or two simple continuous fever, when diuretics, saline cathartics, low diet, rest in bed, are unavailing, and when there are inappetence, some prostration, slight elevation of temperature in the afternoons, now and then chilly sensations with a degree or two of lowering of temperature, some enlargement of the spleen, and urine practically normal? Perhaps we should, were it not that either moderately large or frequently repeated doses of quinine, Warburg's tincture, or, better still, the compound tincture of bark, cure these cases eventually.

It is a widespread conviction in the profession that quinine must and will cure malarial fever.[1] Is this true? Time and again I have given by the mouth or rectum large repeated doses of quinine in solution, and the fever continued. In many of these cases Huxham's tincture of bark in teaspoonful doses every two or three hours gave the happiest results, and soon my patient was entirely well. When this has been true, the blood usually showed a certain degree of anæmia. There were no visible change in the form of the blood globules, no marked increase of leucocytes (rather a diminution), but a marked lowering of the hæmoglobin and of the number of the red cells. No doubt the constituents of the bark which are soluble by percolation with alcohol are valuable as tonics. Among these we should put the extractive matters, notably cincho-tannic acid.

The older authors understood much better than we do the importance of these substances in overcoming the humoral changes causing or resulting from malaria. No oneco uld read the treatise on fevers written by Huxham more than a hundred years ago (London, 1767) without being convinced of the great value he attached to the use of suitable products of calisaya bark.

In Huxham's original formula there is also Virginia snakeroot, and of the combined drugs "he gave one drachm to half an ounce every fourth, sixth, or eighth hour, with ten, fifteen, or twenty drops of elixir vitrioli out of any appropriate draught, or diluted wine."

"I very well know," writes Huxham, "it will sometimes succeed in intermittents when the bark in substance or decoction will not easily sit with the patients. The above composition tends to strengthen the solids, to prevent the further dissolution and corruption of the blood, and in the event to restore the crasis."

Huxham evidently attributed considerable importance to the use of an astringent generous red wine, and also to that of some acid, and especially the elixir of vitriol. Aromatics are also not undervalued by him.

Robert Jackson,[2] writing somewhat later (1795), affirms that "bark alone undoubtedly has a right to be considered as a specific in the cure of the intermitting fever, but its virtues are occasionally improved by the addition of aromatics, chalybeates, and partic-

[1] Read at a meeting of the New York Academy of Medicine, January 6, 1898.

[1] Many eminent medical writers also support this opinion.

[2] "Treatise on Fevers," Philadelphia, 1795, pp. 210, 211.

ularly by a certain proportion of snakeroot. Virginia snakeroot joined with the Peruvian bark was often observed to produce very excellent effects. The cures were more complete and permanent. There was not only less tendency to relapse, but dysenteries and dropsies were more rare after I was fortunate enough to adopt this mode of practice than they had been during the preceding years."

In later times this conviction about the utility of bark has been strengthened by the reports of travellers in South America. Thus Tschudi, as a result of observation during his travels in Peru, states that "the inhabitants of the Peruvian forests drink an infusion of the green bark as a remedy for intermittent fever." He also "found the fresh bark more efficacious than the dried, as in less than half the usual dose it not only effects cures in a short time but insures the patient against the return of the disease." [1]

Good bark contains mainly two different substances, the alkaloids or febrifuge principles and tannin, the tonic ingredient. Among the tonic preparations the extract and wine of bark contain the most tannin of a special kind, and owe their properties doubtless to it.

In the quinine wine of the French codex the quantity of the alkaloid is very small—less than a grain to the wineglassful. Such a small quantity of quinine can scarcely produce any notable tonic effects. Moreover, if the wine of quinine be made with a highly colored wine containing a notable quantity of tannin, the quinine is precipitated by the latter and remains on the filter.

The revisers of the codex have recognized the therapeutic value of tannin in tonic wines of bark by substituting the Huanaco bark in double quantity for the calisaya bark, mainly because this bark contains a large amount of tannin and only a small quantity of the alkaloids of the bark. Only very lately F. Alix[2] advocates the use of tannin in cases of malaria that have resisted ordinary quinine treatment. The tannin is given in solution. Alix cites several successful cases in illustration of the virtues of this treatment, which he says "is remarkably efficacious." To expect such good or lasting effects from even massive doses of quinine will prove delusory, in my judgment, in the highest degree. This statement will be difficult to prove in our mere hospital experience, for the reason that the mild forms of paludism, as shown by continuous moderate elevation of temperature with slight diurnal changes, are not often under treatment in hospital wards. Moreover, when they are, do we not find the cases complicated with other numerous signs of disease? I object very much to hospital studies being made largely or solely the basis of views which should control the practice of medicine without appeal.

In Vol. II., p. 742, of T. Clifford Allbutt's "System of Medicine," and in the last sentence of the article on malarial fever, it is stated that "the physician who at this day cannot treat malarial fevers successfully with quinine should abandon the practice of medicine." Such a sweeping diatribe is scarcely becoming, it seems to me, from the writer of a classical article in an authoritative work. It is doubly objectionable when it is unsupported by certain closely observed facts of important clinical significance. In the first place there are personal idiosyncrasies everywhere to be met and viewed in this light. We know many patients who simply cannot take quinine. It produces nausea or vomiting, aural congestion with tinnitus, skin eruptions of different characters, not to speak of very depressing effects upon the general circulation. This is not invariably true of bark even with these patients, and to numerous other patients the administration of the bark promotes appetite, nutrition, and general well being.

At the present time I have under my care a patient, a young woman with a good appetite, regular bowels, menses normal, urine in sufficient quantity, containing neither albumin nor sugar. For some days or weeks this patient has had daily and irregular moderate elevations of temperature, followed by no appreciable sweats. At certain times, but particularly about one or two o'clock in the afternoon, the temperature becomes subnormal, with or without slight chilliness. A week or two of the treatment with Huxham's tincture of bark brought back a normal range of temperature and led to the disappearance of chilly feelings, and of the general depression and malaise previously alleged by the patient.

When the blood of these patients is examined microscopically for the presence of the hæmatozoön malariæ, the result is usually negative. We cannot therefore be guided in this manner as to a positive diagnosis. As to the spleen, the rule is that it is not much enlarged. We may or may not be able to find its edge under the free border of the ribs; we may indeed find increased percussion dulness over its site, but even this examination frequently remains doubtful. The abdomen is sometimes very tense, which prevents proper palpation, or the abdominal walls are very thick from deposited fat, and this interferes with the examination. If we eliminate the microscopical examination of the blood and the precise limitations of the splenic dulness as guides to the diagnosis of malarial fever, we are forced to abide by our interpretation of the symptoms presented by the patient, by the previous history, ambient conditions, and particularly the kind and effects of treatment. The idea, far too prevalent in my opinion, that malarial fever is rarely if ever endemic in New York City is not borne out by the frequent, almost daily experience of medical practitioners; not that I wish to affirm, nor do I believe, that the marked intermittent forms of tertian type are at all usual among the better class of people, but the mild continuous type is surely prevalent, and to this form I direct particular attention.

It has always appeared to me that the characteristic behavior of a child suffering with malaria is very valuable in aiding us to make a correct diagnosis. It is no infrequent experience for me to be told by the mother or guardian that a small child who had been bright and gay, romping, playing, talking, laughing, almost immediately became languid, quiet, and indifferent, averse to movement or conversation, with or without rise of temperature. A sudden change from the appearance of happy, exuberant health and spirits to a condition of morbid feeling and action without apparent cause, is certainly very striking and often means malaria. After an hour or two of this protracted condition the child will ordinarily begin to notice and play around, slowly at first, but little by little with all its energy and abundant *entrain*. There may be no evidence of chill, no sweating; sometimes fever, sometimes none; no marked digestive disturbance, no cutaneous manifestations. "Malaria," writes Dr. Holt,[1] "is more frequently overlooked in young children than in later life, from the fact that its forms are more irregular." In this way the impression has become pretty general that children are less liable than adults to have attacks of malaria. The contrary is doubtless true, and certainly in my experience, as in that of Holt, children suffering from these manifestations are frequently met with. By means of calisaya bark repeated several times a day in appropriate doses for a week or more, all previous symptoms of malaria will disappear completely. Occasionally there will

[1] "Diseases of Infancy and Childhood." New York, 1897, p. 1,076.

be no reappearance of these manifestations for many months. If the slightest cold be taken, or if there be overfatigue or indiscretions of diet, another outbreak may at any time occur. Speaking in regard to children, Holt[1] writes, "Malarial attacks are particularly liable to occur when the general health is reduced by derangement of the digestive organs." I have no doubt of the truth of this statement, but it is also true and even more so than with the adult, that digestive disturbances are frequently directly caused by the presence of the malarial parasite and can be cured only when this is recognized and properly treated. My experience of many years of summer practice, when I have taken care of numerous children, has convinced me of the importance of this fact. These cases are not always apyretic. On the contrary the temperature will frequently rise several degrees in a short time, and we are often in legitimate doubt after the most careful inquiry and research as to the nature of the disease. In summer practice, by the sea especially, such cases are frequent, but fortunately certain manifestations of malaria are there readily discovered.

For one or other reason the microscopical examination of the blood for malarial organisms is more fruitful than elsewhere, apparently. The sea air seems to have the power of bringing the plasmodium into the blood so that it can be easily discovered. This fact I have been able to observe or become familiar with on several occasions. One of the changes occasioned by the malarial poison is that of the mucous membrane of the upper respiratory tract. We constantly meet with cough, paroxysmal and obstinate in character, with little or no expectoration, which is obviously under the dependence of the malarial dyscrasia. In these cases the ordinary cough mixtures aided with sprays and local applications, soothing or astringent, remain inactive unless the constitutional state be considered.

We are not inclined as a rule to look for malaria when it is a question of the differential diagnosis of a cutaneous lesion. And yet that various eruptive diseases are thus occasioned is to my mind unquestionable. I have seen a general erythematous or papular rash, very much resembling that of scarlatina or measles, inaugurate with the chill an attack of intermittent fever. I have seen an invasion of general furuncular disease in a child, which remained obstinate and painful for many weeks, and was relieved ultimately only by frequent doses of the compound tincture of bark.

It is a matter of common knowledge, the unpleasant congestive effects caused by quinine upon the aural circulation. The evil effects, however, are not seen in anything like the same degree in different persons. While some persons cannot take more than a minute dose of quinine without having their head ring and their ears become painful or noisy, others bear moderate or even large doses with impunity and complain very little of tinnitus. Manson,[2] in speaking of quinine, writes: "There are undoubtedly cases of malarial disease in which quinine fails, and there are not a few cases in which, acting more or less as a poison, it cannot be used in effective doses, and in which some substitute for it would be most useful." I am inclined to believe that the mode of administration has something to do with the effects of quinine upon the ear, and that it is really better borne in aural troubles when administered in rectal injections than when it is given by the stomach. The idea formerly prevalent not to give a large or even moderate dose of quinine by the mouth, if the tongue was at all coated, or there were other signs of biliary derangement, is to-day not seldom lost sight of. It is true that in some hospital services a dose of calomel or blue mass is given at the beginning of the treatment with quinine, but it is rarely repeated, and, moreover, the quinine itself is not suspected of producing injurious effects upon the stomach.

It is probable that one reason why Warburg's tincture or extract is frequently efficacious in arresting attacks of malarial fever, especially in instances somewhat chronic in type, is on account of its decided action on the liver and bowels. Apart from its well-known antimalarial repute, I know of one physician, lately deceased, who had a very large experience of its value and who told me that this was the manner in which he estimated it, viz., as a very important cholagogue. There are many ways in which malarial infection can take place which are rarely suspected. One is through open furnace flues communicating through the furnace and cold-air box immediately with damp, uncemented cellars or area ways. When the fire of the furnace is burning very little, or, again, when it is entirely out and the flues are left open, the upward draught carries such air directly into bedchambers, and indeed into every part of the house. If in some houses the soil pipe or main drain of the house is defective, the effects of sewer gas are often added to those conditions breeding malarial fever. I have no doubt in my own mind that sewer-gas poisoning and the infection of the system with malarial germs are often confounded. In point of fact, many of the symptoms occasioned by one or other kind of poisoning are similar, and it is unquestionable that quinine or some preparation of cinchona bark will produce curative results in the treatment of both classes of disease.

In the chronic forms of malarial poisoning in which with a moderate grade of anæmia there are a marked depression of the vital forces, repeated attacks of neuralgia in various regions of the body, and circulatory as well as renal disturbances marking functional inadequacy, no treatment will avail much unless it be a suitable and prolonged change of climate. Nothing will benefit some of these patients to the same degree as their transport inland to a high mountainous region for a more or less prolonged period. I recall two of my patients of this kind, to whom a lengthy sojourn at St. Moritz in the Engadine was of very great benefit. In many cases of malarial poisoning and in certain constitutions a permanent cure is established only, if ever, by many years of careful attention to their habits and surroundings. And even when these are suitable and healthful, these patients will be obliged to take an occasional antimalarial treatment. In some cases of chronic malaria I have used the eau de la Bourboule, a natural arsenical water, with great advantage. From one to three ounces of this water after meals is a sufficient dose. Some of these malarial patients are more particularly affected with disturbances of the digestive tract and a coated tongue; flatulence and disturbed stomach and intestinal digestion of this origin are not seldom met with by me. The digestive annoyance may be that of obstinate constipation: again, it is a disposition to chronic diarrhœa. Sometimes the diarrhœa and constipation alternate in such a way that our efforts to bring about healthy digestion and assimilation of food are at times disheartening. We may use on the one hand mercurials in small repeated or occasional large doses, combined or not with appropriate carminatives or cholagogues. We may try soda, bismuth, or different antiseptic salts, like beta-naphthol or the sulphocarbolates, with or without vegetable charcoal, and yet until we get the system properly influenced with one of the preparations of cinchona our remedial interference occasionally remains fruitless.

One of my patients, a young lawyer of New York, is an instance of the sort I refer to. Many years ago

[1] "Diseases of Infancy," p. 1,070.
[2] "Year Book of Treatment," 1896, p. 410.

he contracted Chagres fever in South America, and for several years whenever I examined his blood microscopically I found more or less free pigment in it. On account of his stomachal disturbances he went abroad, and was more or less under medical and dietetic treatment during eighteen months. He travelled in different countries, made of course a sea voyage to and from Europe, and yet even now he has occasional febrile attacks with concomitant diarrhœa, furred tongue, foul breath, relaxed throat, and irritative cough. I am obliged in his case to depend upon the combined use of quinine, iron, and arsenic to bring his attacks to a satisfactory termination. One formula used is that of reduced iron, arsenious acid, and sulphate of quinine; the other is the citrate of iron and quinine, arsenious acid, with one-quarter of a grain of extract of nux vomica and a little extract of henbane added, so as to invigorate his impaired nervous system and reduce in a measure the irritative effects of the arsenic on the alimentary tract.

Ordinarily we expect malarial fevers to be generated in low-lying, badly drained districts, near watercourses where there are decaying organic matter and marked elevation of temperature. We must not ignore the fact, however, that in a rocky soil where the substratum is clay, and the soil therefore very impermeable at times, the stagnation of water under the surface will breed malarial fever of a pronounced type. I have had experience with just this kind of malarial product, and, although some text-books may refer to the possibility of its development under these conditions, it is not ordinarily accepted or believed.

In regard to the use of the sulphate or other salts of quinine as compared with the compound tincture of cinchona, I have had much the same experience that Trousseau has had.[1] In the treatment of mild forms of malarial fever, while the preparations of bark may not act so rapidly as quinine, they are often more efficacious. After the paroxysms have once been arrested they are not so apt to recur. If the bark is given continuously for several weeks, we shall find that the patient's general condition is much better than it is in those cases in which quinine in small or moderate doses has been persistently taken. The anæmia is less marked, the appetite is keener, the strength is less impaired. Moreover, we are not apt to have œdematous infiltration of tissues, or that subicteric, cachectic look which is often met with in patients who have taken quinine for too prolonged a period.

As to the spleen, I would simply affirm that, despite repeated statements to the contrary, this organ will often remain without notable degree of enlargement or local tenderness, although the presence of the malarial poisoning is unquestionable. Of course it should be understood that in intense forms of malarial fever, or whenever there is a suspicion even that a pernicious form of fever may suddenly develop, we must make use of the quinine salts immediately and in large doses, until the paroxysms are broken up; but after these have disappeared for a week or more it is then judicious and timely to substitute for them the use of a suitable preparation of bark, given in fairly large doses, frequently repeated. I usually order under these circumstances one drachm of the compound tincture every two or three hours. In some instances I make use of the bark combined with nux vomica or strychnine. As a substitute for the compound tincture of bark I would suggest the use of the compound fluid extract of bark. This preparation is devoid of the alcohol of the compound tincture and is five times as strong. Both of these facts add to its value. It may be given in glycerin, simple elixir, or some palatable syrup with water, in doses of one-fourth to a teaspoonful, according to circumstances.

[1] Clinique Médicale, vol. iii., pp. 476–489.

Some of us doubtless remember a former house physician of Bellevue Hospital, Dr. Gaspar Griswold, whose untimely death brought to a close what promised to be a very brilliant medical career. In August, 1879, Dr. Griswold published, in the New York Medical Record (page 150), a short but very convincing article on "Pilocarpine in Intermittent Fever." In this article Dr. Griswold claimed that he had practically aborted paroxysms of intermittent fever with one-fifth grain of muriate of pilocarpine, administered hypodermically. This was accomplished without any bad after-effect, no depression, no ptyalism. Dr. Griswold also claimed for pilocarpine that it not only abated the paroxysm during which it was employed, but also prevented the return of future paroxysms. In this manner pilocarpine became a direct and very important adjunct to quinine or the cinchona preparations in the cure of intermittent fever, especially of the tertian type. Upon several occasions since reading Dr. Griswold's article I have made use of pilocarpine hypodermically. I have, it is true, seen some good effects and results from its use, but never to the degree and in the manner reported by Dr. Griswold. To be just to a distinguished observer, I should add that I have never been willing to give as much as one-fifth grain, but have limited myself to one-tenth or one-twelfth grain, as I consider these doses safer in view of possible œdema of the lungs caused by pilocarpine.[1] For my own part, in order to meet the indications of the chill of a malarial paroxysm, I know of nothing superior to a large dose of chloric ether, or a hypodermic of morphine and atropine. While neither of these has the power to abort or cut short the chill, they both will promote in a greater or less degree the comfort and well being of the patient, and for this reason should be supported by good medical authority. In a similar manner I am disposed to recommend occasionally the use of the hot-air bath.

In terminating this clinical paper, I wish to refer to a very able article which appeared from the pen of Prof. William Osler, in the *Medical News*, March 6, 1897, on "The Diagnosis of Malarial Fever," and which previously, on February 22, 1897, was read before the Medical Society of the County of New York. Although in the main no one could disagree with the report and findings of this distinguished observer, yet it may be permitted to me to criticise it from two points of view: First, because of the very positive way in which Osler affirms that, without the presence of the malarial parasite, there is no malaria. Despite this statement, Osler admits that there are instances in which it is only after repeated and most careful examinations on the part of experts that this organism can be found. He does not believe that it may occasionally be absent. In this view I believe he is too dogmatic. Again, Osler states that "other maladies, a motley host, from headache to biliousness, from keratitis to chilblains," are attributed to "a touch of malaria."

This judgment may be true of very ignorant practitioners, but must not be permitted to include many men who are close observers and intelligent in their particular fields of work, and who are obliged to admit that no other diagnosis than that of malaria will fit many cases, despite the absence of special organisms, and no other treatment than a suitable preparation of cinchona bark will cure their fever in a reasonable time, or prevent frequent or serious relapses.

Again, even if it be admitted that in all cases of malarial fever the plasmodium is present at some time in the blood, and when not discovered merely

[1] I shall never forget a fatal case of œdema of the lungs occasioned many years ago by a too large dose of jaborandi per rectum.

proves the lack of skill or patience in the search for it, yet this fact should not interfere with the due appreciation of the other clinical phenomena indicating malaria. These phenomena, when estimated carefully and all sources of error eliminated as far as possible, have enabled physicians in the past quite generally to make an accurate diagnosis, and should not be underestimated.

To illustrate my position, let us take as an analogous example pulmonary tuberculosis. Of course, whenever Koch's bacillus can be discovered in the sputa, a positive diagnosis can be given from this fact alone; yet there are numerous instances in which for long periods—it may be weeks or months—there are no sputa, and no bacilli can therefore be found. Despite this fact, the other signs and symptoms point almost indubitably to the presence of tuberculous disease. Sometimes, not to say frequently, at a later period bacilli are found, and the diagnosis is rendered absolutely positive. In a few instances, it is true, bacilli are never found. It behooves us, however, in either case to institute the best advised antituberculous treatment, and in some degree at least to have our judgment reaffirmed by the apparent or evident result of it. Certainly it would not be wise or conscionable to withhold antituberculous treatment in doubtful cases, or when we could say only that tubercle was present, partly in view of the signs we had actually found and partly because no other disease so nearly approximated the condition already discovered.

Thus it is with the diagnosis of malaria in many instances. We do not find after careful search the plasmodium malariæ, we may not have an undoubted antecedent malarial history, the symptoms present may not settle the diagnosis unquestionably, and yet there is no other disease which so nearly approximates what we have before us and are forced to interpret as malarial fever. We apply the touchstone of specific treatment, sometimes after other treatment has been vainly tried, sometimes immediately and in view of a highly probable diagnosis, and very shortly there is great improvement or a rapid temporary cure of our patient.

Are we not, then, still further justified in reaffirming our previous diagnosis, and saying this is malaria?

In conclusion, let me add one word, and it is that while we should give our warm, steadfast adherence to all skilled laboratory work, clinicians should not allow themselves to be wholly influenced by it. There are still numerous sources of error connected with it, not merely or principally as regards technique, but as regards interpretation of one's findings under the microscope. Take diphtheria, for example, and see where we should drift if we take the present laboratory examinations as our sole reliable guide. The Loeffler bacillus is present, and hence we have to do with diphtheria. No Loeffler bacillus is found, and therefore there is no diphtheria. As a clinician, I hold that many of the latter class of cases are to all intents and purposes, outside the laboratory researches, to be regarded as diphtheria. Their care and treatment must be essentially the same, except perhaps in the injection of antitoxin; and to ignore this view is to expose ourselves to regrets and poor success in the management of many of our cases.

At the conclusion of the paper, to give greater emphasis to the statements made regarding the diagnosis by microscopical examination of the blood, Dr. Robinson read a letter from Dr. Frederic E. Soudern. In a case at present under Dr. Robinson's observation, Dr. Soudern had recently been unable to find the plasmodia, although some months previously they had been found in this person's blood by Dr. Harold Ernst, of Boston.

"My Dear Doctor: *A propos* of our conversation this morning, I beg leave to ask your indulgence in the following:

"The plasmodia of malaria are, according to most observations in this climate, in the great majority of cases, found only in the peripheral circulation, during, as well as a limited period before, and a short time after, the period of actual paroxysm, be this of long or short duration. They are then found microscopically in fresh or stained specimens of blood without difficulty.

"In very mild infections they may be very scanty in the peripheral circulation, probably stored up in the inner organs, but a careful search usually reveals a typical picture, on which the diagnosis can be based.

"Attention must be given to Baccelli, who states, in Verhandlungen des XI. Congresses für innere Medicin, Leipzig, 1892, that sometimes severe malarial fevers occur during which it is impossible to make out the presence of plasmodia in the blood. He adds that frequently in the beginning of the attack the parasite cannot be found.

"In those cases of pernicious æstivo-autumnal malaria without a febrile movement parasites may be found, but this condition is very rare. Also in exceptional cases of malarial cachexia without fever the hæmocytozoa may be present, but also very rarely. Consequently I believe that the vast majority of cases observed a longer or shorter period after the actual series of paroxysms, or between such series months apart, do not show plasmodia on examination of the blood.

"The train of symptoms in these instances may probably be attributed to the toxins, of which little is as yet known, or they may have the secondary anæmia as their causative factor, or both. For example, in postmalarial hæmoglobinuria, where a causative factor must still be potent, most frequently plasmodia are not found in the blood by competent observers; and here again we must probably look to one or other, or both, of the above possible etiological factors.

"Yours very faithfully,

"Frederic E. Soudern, M.D."

New York, January 6, 1898.

CLINICAL OBSERVATIONS UPON THE HEART AND CIRCULATION IN DIPHTHERIA.[1]

By HENRY DWIGHT CHAPIN, M.D.,

Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital; Attending Physician to the Post-Graduate, Willard Parker, and Riverside Hospitals; Consulting Physician to the Randall's Island Hospitals.

The various types of diphtheria and their symptomatology afford a wide field for discussion. In this paper it is intended simply to call attention to the heart as affected by diphtheria, as noted by the writer in clinical observations made at the Willard Parker Hospital. In a large percentage of cases the interest and attention of the physician are absorbingly directed to this organ, and the mortality of the disease depends largely upon the way in which it is affected by the poisons generated by the pathological processes. It is not intended here to make an exhaustive study of this subject, but rather to sketch certain clinical types that have been observed in the hospital. The so-called septic type is usually followed to a fatal termination by a persistent and powerfully depressant action upon the heart. In these cases there is a profuse membrane covering tonsils, uvula, and soft palate, with plugged nostrils and sometimes epistaxis. A peculiar fetor exhales from these secretions, and more or less adenitis is present. At times hemorrhagic spots

[1] Read at a stated meeting of the New York Academy of Medicine, January 6, 1898.

upon the skin may be noted. While the kidneys and various other organs are crippled in such an attack, death nearly always results from a steady and more or less rapid failure of the heart, upon which the most stimulating treatment appears to have little effect. It is small wonder that this is the case, as the organ has to contend not only with the toxins of diphtheria, but with what appears to be a general septic poisoning, shown by extreme pallor, persistent vomiting, and stupor. While various grades of uræmia may be present, all of these portentous symptoms may appear when the patient is passing a fair amount of urine. A brief synopsis of a few cases may be of interest in this connection, as exhibiting the way these patients act.

Mary McL——, eight years old, had been four days ill on admission. Thick membrane on both tonsils and soft palate; anterior nasal discharge, with nasal obstruction; cervical adenitis. She was given six thousand units of antitoxin, irrigation, feeding, and free stimulation. On admission the pulse was weak and the patient in a somewhat stupid condition. The pulse improved some under stimulation. Five days after admission uncontrollable vomiting began, and continued until the patient's death at the end of the ninth day. At the same time a scarlatiniform rash developed, that was thought to be due to the antitoxin. The temperature varied from normal to 102.5° F. The patient did well until the fifth day after admission, when pallor, stupor, and vomiting, with weak and rapid pulse (112–156), set in, and continued until death.

The occurrence of vomiting in connection with a weak pulse is an exceedingly grave omen. One symptom is apt to be as uncontrollable as the other. The stomach may give out before there are marked evidences of heart failure, but the latter will soon follow. If, in cases in which the pulse is acting badly, vomiting begins, the former condition will prove most intractable, even to hypodermic stimulation.

Frank D——, three years old, had been ill for three days on admission. Thick yellow membrane on both tonsils and sides of uvula, extending on to hard palate; anterior nasal discharge and nose partly plugged; cervical adenitis. The patient did quite well for four days, but had several attacks of epistaxis. On the fifth day he began to vomit. This improved under stomach washing, calomel, and rectal feeding, but began again later. It was not accompanied at first by pallor and stupor, and was not thought to be especially serious. The pulse was weak on admission, but improved somewhat under treatment. It soon grew weak again, and during the day before the patient died it was almost imperceptible—125 to 135. The temperature was irregular, between 100° and 102° F. He died ten days after admission. He was first given twenty-five hundred units of antitoxin, and afterward two thousand units.

Lillie F——, seven years old, three days ill on admission. Thick gray membrane on both tonsils and pillars of fauces; profuse anterior nasal discharge and one nostril plugged; slight bilateral adenitis. The throat cleared of membrane six days after admission, but it partly reformed later. On admission pulse was of good quality. Six days later pallor began to be marked. Next day the patient was somewhat drowsy and the pulse showed signs of weakness. At the same time the temperature rose abruptly to 104.8 F., and an otitis media developed, the drum rupturing nine days after admission. The pulse continued weak, and two days later uncontrollable vomiting set in. The pulse grew weaker, very rapid, and irregular, in spite of frequent hypodermic stimulation. The patient grew very restless, and died on the thirteenth day of the disease. Forty-five hundred units of antitoxin was given on admission, and twenty-five hundred units on day of death.

Emma H——, four years old, sick four days, with thick white membrane covering tonsils, uvula, and posterior part of hard palate; both nostrils plugged. On admission the pulse was quite weak. This improved and the patient did well for five days, but was very pale. The throat and nose were now practically clear. Five days after admission the pulse became rapid and very feeble. Two days later vomiting began, both ears discharging. Eleven days after admission there was regurgitation. The vomiting and feeble heart action, with stupor alternating with delirium, continued until the patient's death on the thirteenth day after admission. The temperature was irregular, from 100° to 103° F. Twenty-five hundred units of antitoxin was given on admission, and two thousand units on the following day.

A distinct and marked slowing of the pulse rate is a peculiarity not infrequently noted in these grave cases. While the quality of the pulse is more important in prognosis than the mere rate, yet the latter may be of grave significance. The slowing may take place before or after a marked quickening. The prognosis will depend upon the degree of slowness, which, if extreme, is always followed by a fatal ending.

Elsie F——, eight years old, had been six days ill. Thin gray shreds of membrane scattered over pillars of fauces and tonsils; bloody anterior nasal discharge; bilateral cervical adenitis. On admission the patient was in a semistupid condition, with marked pallor. Pulse, 120, and of fair force. Regurgitation two days after admission. Two days later the pulse became very soft and weak, and dropped to 60, continuing slow and weak until the patient died, three days later. Vomiting set in on the same day that the pulse became slow. Five thousand units of antitoxin was given on admission, followed by hypodermics of whiskey and strychnine during period of heart failure.

James McC——, seven and one-half years old, had been three days ill. Both tonsils, anterior pillars of fauces, and uvula were covered by white membrane; nasal obstruction; bilateral cervical adenitis. On admission the patient was very pale, but the mental condition and pulse were fairly good. Two days after admission vomiting began, and continued until the patient's death on the fifth day. At the same time the pulse became very weak, with a rate from 115 to 120. On the day before his death the pulse dropped to 42, remaining slow until death. The temperature varied from 100° to 102.6° F. The urine contained much albumin, but was passed in sufficient amount. No œdema. Hemorrhagic spots over body. On admission twenty-four hundred units of antitoxin was given, and later eighteen hundred units. Free stimulation.

Lillie M——, four and one-half years old, had been ill for two days. Thick gray membrane on both tonsils and pillars of fauces; both nostrils plugged; cervical adenitis. For the first three days after admission the pulse was of fairly good quality, although somewhat rapid. On the fourth day it dropped from 128 to 66, but the strength was not decreased. The next day it became rapid and feeble (120 to 138); the patient developed stupor and vomiting, which continued until her death, three days later. We have here the remarkable phenomenon of a slow pulse lasting about twenty-four hours in the middle of her illness, preceded and followed by rapid heart action. Temperature from 98° to 100° F. Purpuric spots over body. On admission six thousand units of antitoxin was given. Free hypodermic stimulation.

The following case presented a slow pulse on admission:

Cicato G——, six and one-half years old. Thin gray membrane on both tonsils, sides of uvula, and pillars of fauces, but the membrane was beginning to disappear. On admission the patient was in a stupid

condition. The pulse was slow (60), but regular and of fair strength. It improved for a day under stimulation, but then became very slow, dropping to 38, and irregular. Vomiting set in on the second day and continued until death, three days later. The pulse was regular, with good rate and form (104), on the day before death. On the day of his death it had the same rate, but was irregular. There was vomiting of old blood clots, probably from epistaxis. No pyrexia. He died suddenly, after convulsions. On admission fifteen hundred units of antitoxin was given.

The most remarkable case of slow pulse in my service occurred in a boy of five years. For a few days after admission he had rapid heart action, then the pulse began to slow up, and in a few days his heart beat was only 28 to the minute. He died after two days of this extremely slow pulse. On auscultation the cardiac sounds were fairly distinct. Repeated hypodermics of whiskey, strychnine, and nitroglycerin had absolutely no effect upon the organ.

A slow pulse, however, in the absence of other untoward symptoms, does not necessarily predicate a fatal ending, as is shown by the following case:

Alexander H——, thirteen years old, ill three days. Small patch of yellow exudate on right posterior pillar; also several small patches in crypts of left tonsil. On admission the patient had an intermittent and irregular pulse—rate, 90, and of fair force. After rest in bed and stimulation the pulse improved. In two days the pulse became slow (40), but the patient was bright and presented no symptoms of heart failure. It remained about 40 for three days, at times irregular. The rate then increased (60 to 70), with occasional irregularity, and the patient went on to recovery in about a week. Sixteen hundred units of filtered antitoxin was given, and the usual stimulation.

It occasionally follows that the heart does not succumb in these severe septic cases, but responds enough to free stimulation to tide the patient over the critical point. I have seen a few such instances, of which the following is an example:

Charles S——, four years old, six days ill on admission. Hemorrhagic necrotic membrane on uvula and soft palate; small amount on both tonsils; bilateral cervical adenitis. Pulse rapid and weak. Marked pallor and patient somewhat stupid. Urine loaded with albumin and blood cells. He improved slowly during the next six days, the membrane completely disappearing. The pulse then became exceedingly rapid, irregular, and weak, showing a double dicrotism that made it exceedingly difficult to count. Vomiting began, and all medication by mouth was discontinued, stimulation being given hypodermically and by rectum. Three days later the stomach recovered its tone, so as to allow moderate feeding and stimulation. Two weeks later the patient left the hospital in fair condition. Twenty-four hundred units of antitoxin was given.

Too much importance cannot be paid to keeping the patient quiet in a recumbent position until the heart completely recovers its tone in these severe septic cases. The depression of its function may persist for weeks after all exudation has disappeared, and indeed every other manifestation of disease. A physician who entered the hospital with tonsils and palate covered with membrane insisted upon leaving between the second and third week. His pulse was feeble and he was warned of danger. Shortly after his departure he died suddenly of heart failure.

When the local manifestation of the disease is slight and there is no sepsis, the heart may suffer comparatively little. There seems to be a direct ratio between the amount and character of the local inflammatory process and exudation, and the nature and severity of the constitutional symptoms, especially as regards the heart. In mild diphtheria a rapid or irregular pulse, without other constitutional symptoms, does not seem to portend the danger that the same action does in severe septic cases. In a number of instances an irregular pulse during convalescence has been improved by letting the child get out of bed. For example:

Minnie C——, ten years old, sick two days on admission. Thick yellowish deposit on right tonsil. The patient was pale and poorly nourished, and the day after admission the pulse became irregular in force and frequency. Free stimulation ordered. No vomiting or pains, and mental condition good. During the next few days the general condition markedly improved, but the pulse continued irregular, the stimulation apparently not affecting it. On the twelfth day she was very bright and well, except for the irregular pulse, and she was allowed to sit up. No effect on the pulse, except a slight improvement in regularity. She was then up daily until her discharge on the sixteenth day, when the pulse was of good force and almost entirely regular. She was given two thousand units of antitoxin on admission.

An irregular or intermittent pulse, without symptoms of prostration, cannot have the same significance as when the two coexist, as shown by this and similar cases. Physical signs referred to one organ must to a certain extent be interpreted by the way other organs are acting and by general rational signs.

During the course of diphtheria, as well as during convalescence, the heart must be most carefully watched. If it responds to stimulation the case is correspondingly hopeful. In the grave type of the disease cited in the first few cases, no stimulation has any effect upon the heart. All stimulants have been tried, but reliance is placed principally upon whiskey, strychnine, nitroglycerin, and, in some cases, digitalis. When vomiting begins, with pallor and stupor, frequent hypodermic stimulation is employed, as it is useless to try the stomach, which rejects everything.

Not infrequently children lose their lives because they cannot be kept quiet, but insist on sitting up in bed or tossing about. Small doses of morphine given hypodermically are most effectual when the pulse is weak and irregular and the child very restless. After a hypodermic they lie quietly, and thus the heart is relieved of extra strain. The direct action of non-narcotic doses of morphine upon the heart is likewise steadying and stimulating.

In the clinical study and observation of cases at the hospital, the writer is indebted to Dr. Poor, of the staff, for aid and co-operation.

Aphasia.—The object of treatment is to restore the conduction of impulses along the usual paths or to open up new paths. In amnesic aphasia, endeavor to strengthen the defective recollection of words. Learn the words by heart, and then adopt short reading-exercises. The exercises should be performed in front of a mirror, so as to enable one to recall the memory of the necessary movements. In motor aphasia other parts of the brain may take on function. Single sounds, then syllables, and then words, are taught. Along with the articulation exercises, writing-exercises with the left hand should be performed. Teach the patient to form words from printed letters. Sensory aphasia is far more difficult to teach. First attempts are made by means of written language. Develop lip reading, combining with it reading, writing, and other exercises. These cases are often complicated with a combination of different forms of aphasia. Much patience is required. Results so far encourage further efforts. — KARL BOK, *Festschr. des Stuttgart. aerztl. Vereins*, 1897.

FURTHER STUDIES (THIRD SERIES) ON THE GONOCOCCUS* (NEISSER).†

By HENRY HEIMAN, M.D.,

NEW YORK.

In my second paper, entitled "A Further Study of the Biology of the Gonococcus," etc.,[1] I called attention to the comparatively long viability of the gonococcus in liquid culture media, such as liquid chest-serum plus nutrient broth, etc. The experiments of transplanting the gonococcus on such liquid media I continued, and after eighty-two days I was still able to find the gonococcus by transplanting the same from the liquid medium on chest-serum agar, but not in cover-glass preparations. Recognizing the fact that the gonococcus had been found in the exudates of chronic urethritis cases of four years' standing or more, I was anxious to determine the number of times it was possible to transplant the gonococcus from its original culture medium to other similar media. I therefore substituted the following experiments:

First, I planted the gonococcus on chest-serum agar and then transplanted the same every fifth or sixth day on a chest-serum agar tube. This experiment I repeated twenty-five times, showing that the gonococcus can be transplanted probably indefinitely under proper conditions. This fact very likely accounts for those cases of chronic gonorrhœal urethritis of years' standing which still present the gonococcus in cover-glass preparations and culture media. This set of cases must not be confounded with those cases of chronic urethritis in which an old gonorrhœal infection is accountable for the diseased urethra. This observation was made by Wassermann,[2] who showed that gonococci produce toxins, and that gonococci cadavers contain these toxins and remain toxic for a long time. Wassermann's experiments show that chronic urethritis may exist as a result of the gonococcus directly, or of its toxin products indirectly, and that injections of these toxic materials are followed by pathological conditions of the urethra. In corroboration of these facts I hereby present the following schedule, showing fifteen cases of chronic urethritis sent to me for culture experiments, which were pronounced cured by their medical attendant.

TABLE I.—EXAMINATIONS OF GONORRHŒAL THREADS OF CHRONIC URETHRITIS CASES WITH COVER-GLASS AND CULTURE MEDIA BY MEANS OF THE CENTRIFUGE.

Number of Injection.	Duration of Disease.	Condition of Urine.	Cover Glass.		Cultures.		Number of Cases.	Percentage.		Remarks.

* This paper is based upon experiments conducted in the bacterial laboratory, department of pathology of the College of Physicians and Surgeons, Columbia University, New York

† Read at the meeting of the genito-urinary section, New York Academy of Medicine, December 14, 1897.

The urine of most of these cases showed threads, and in no single case, as the table will show, was the gonococcus demonstrable by cover-glass preparations and culture media.

In the last edition of Bouchard's[3] "Pathology" the statement is made that Strauss, Pescione, and Eraud claim to have found the gonococcus in the normal urethra. The opinion to which my observation leads me is entirely at variance with that of the above-named writers. I believe that the gonococcus does not exist in the normal urethra. In reading the published reports of the experiments of Strauss, Pescione, and Eraud, I find that their work was deficient in that they did not avail themselves at that time (1889 and 1890) in their experiments of either culture media or of Gram's stain. Strauss[4] cites the case of a boy, sixteen years of age, in whom he found the gonococcus. The boy was of weak constitution, a confirmed masturbator, and he claims the boy masturbated last eight days before the purulent discharge made its appearance. Strauss simply used ordinary aniline dyes for staining, and concludes that the gonococcus may be an unoffensive host, an ordinary saprophyte in a healthy urethra, and that through such irritation the gonococcus may invade the epithelium and produce a catarrhal condition. Pescione's[5] experiments are in the same line, and his conclusions are similar to those of Strauss. Eraud[6] publishes similar histories, based on experiments, which were questioned even at that time by Verchère. The fact that we cannot in every instance, particularly in the vulvo-vaginitis of children, trace the source of infection, by no means justifies us in believing that the gonococcus has a normal habitat in the urethra or in the vulvo-vaginal tract of children. A former paper[7] on the gonococcus (*q. v.*) fully covers this point. A most interesting fact in the life history of the gonococcus in connection with this point was demonstrated by Welander's[8] experiments. He caused flies to be dipped in gonorrhœal pus and then allowed them to fly about and land upon suitable culture media. At the expiration of three hours he could still demonstrate gonococci colonies on culture media. The theory that a diplococcus exists as a saprophyte in the normal urethra, and that it develops under certain favorable conditions into the gonococcus, is certainly questionable.

Rectal Gonorrhœa.—Rectal gonorrhœa undoubtedly occurs more frequently than is usually believed or recognized, especially in women. In a paper by Baer,[9] the author found sixty-seven out of one hundred and ninety-one cases of gonorrhœa to be suffering from rectal gonorrhœa. He did not, however, succeed in cultivations from the rectal secretions. Schultz[10] found fourteen out of one hundred and seventy-four gonorrhœal cases to be suffering from rectal gonorrhœa. *En passant*, I beg to report four cases of rectal gonorrhœa, in two of which I was enabled to demonstrate the gonococcus not only with cover-glass preparations, but also by culture media.

CASE I.—Female, single, aged nineteen years; presented rectal and vaginal discharges. Dispensary patient of Dr. Moskowitz. The rectal symptoms predominated and caused her to seek medical advice. This patient's hymen seemed to be intact, and she stated that intercourse occurred in the standing position and she was unable to tell whether her vagina or rectum was entered. The rectal secretions were examined with cover-glass preparations and by culture media, with positive results.

CASE II.—Female, aged twenty-four years, married three months. Patient of Dr. Brettauer. Husband had chronic gonorrhœa. This patient suffered from endometritis, bartholinitis; as a result of the last an abscess formed and ruptured into the rectum, causing the rectal gonorrhœa. The rectal discharges were

examined by me with cover-glass preparations by Gram's method and with culture media, with positive results.

My other two cases were examined only by cover-glass preparations (Gram's stain), with positive results. In the one case of a boy the infection occurred through pederasty; in the other, a female child, three years old, who originally suffered from an ischio-rectal abscess, the infection occurred from a vulvo-vaginitis, which she acquired in a hospital.

Gonorrhœal Arthritis.—The following four cases of gonorrhœal joint affections that came within my own observations are of interest in connection with the study of the gonococcus. In two of them the experiment included culture media.

Case I.—Newborn female child, patient of Dr. Jarecky. In this case the joint affection followed a gonorrhœal ophthalmia, which made its appearance on the sixth day after birth. Two weeks later the small finger of the right hand became swollen, and forty-eight hours later the left wrist became similarly affected; three days later the left great toe was found swollen, and presented all the symptoms of an acute inflammatory process. An incision into the toe revealed an infiltration and a little pus. The following day, when I first saw the case, we found the wound closed and covered with a crust, which was removed and the wound reopened. We could then detect a focus of pus, which was utilized for experimental purposes. Cover-glass preparations were made and examined by Gram's method, gonococci being found in considerable number.

Case II.—Female child, eleven years old, suffering from vulvo-vaginitis, in the discharges of which gonococci were found in cover-glass preparations (Gram's method). The left elbow-joint became swollen and fluctuating two weeks after the vulvo-vaginal infection. The aspiration of the elbow-joint showed a serous effusion. The examination for gonococci with cover-glass preparation gave a negative result.

Case III.—Male patient, aged seventeen years, with acute gonorrhœa. On the twenty-fifth day after infection an acute inflammatory process appeared in the right wrist, with pains in the left ankle, right shoulder, and left wrist. I aspirated the right wrist three weeks after the swelling first made its appearance here; a little effusion was removed and examined by cover-glass preparations and culture media, with negative results. The urethral secretion gave a positive result with culture media.

Case IV.—Male, aged twenty-eight years, with gonorrhœa of three months' standing. This patient then developed a swelling over the left sterno-clavicular joint, accompanied by a rise of temperature. A probatory puncture revealed a serous fluid free from gonococci. Twenty-four hours later a second puncture revealed pus, in which gonococci were found by cover-glass preparation and culture media. I need hardly state that in both instances the syringe employed and place of puncture were rendered thoroughly aseptic.

Inoculations into the Eyes of Newborn Rabbits and Kittens with the Gonococcus (Neisser).—Heller,[11] of Berlin, believing newborn animals more susceptible to gonorrhœal infection than old ones, employed only newborn rabbits in his inoculation experiments. On this account, I also resorted to newborn rabbits and kittens. I first inoculated a series of six newborn rabbits on different days—three on the third day after birth, two on the fifth, and one on the sixth. Of course the lids of the rabbits, being closed, were forced open for inoculation purposes. In this series of experiments the results, as far as the production of gonorrhœal ophthalmia was concerned, were negative, even after the expiration of fourteen days. There was not even a serous discharge as a result of the mechanical irritation depending upon the inoculation. The experiment was performed in the following manner:

The eyelids having been forced open, a sterilized platinum loop was passed under the lids, then withdrawn, and then streaked on chest-serum agar plates. This procedure was for control purposes, no gonococci being demonstrable. Then a pure gonococcus culture was introduced under the lids and was rubbed all over the palpebral conjunctiva. Twenty-four hours later the eye was examined and no discharge was observed. The platinum loop was reinserted under the eyelids, then streaked upon chest-serum agar plates, all with negative results. This procedure was repeated on the second, third, and sixth days after the attempted inoculation, always with a negative result.

For the second series of experiments, six newborn kittens were employed, in each of which an attempt at gonorrhœal injection into the eye was made and in the same manner as before. In all cases the results were negative. Next a rabbit, about one month old, was employed. An irritation of the eye was artificially produced by instilling a few drops of hydric acetate. Before the instillation the mucous membranes of the eye were examined for the presence of the gonococcus, and none found. Forty-eight hours after the instillation of the acid, the conjunctiva of the eye was found swollen and congested, while the cornea was hazy and much secretion was present. An examination of this secretion made with cover-glass preparation and culture medium revealed numerous cocci, but no typical gonococci. I then inoculated the same eye with a pure culture of the gonococcus, and in twenty-four, forty-eight, and seventy-two hours the examination for gonococci gave a negative result.

The following summary of my experiments shows that:

1. The gonococcus can be kept alive in certain liquid culture media as long as eighty-two days.

2. The gonococcus can be transplanted probably indefinitely from one culture medium to another. I succeeded in transplanting it twenty five times.

3. Fifteen cases of chronic urethritis, pronounced on clinical evidence cured, were found to be entirely free from gonococci, as judged by cover-glass preparations and cultures.

4. The statements of Strauss, Pescione, and Eraud, that the gonococcus occurs in the normal urethra, is not satisfactorily proven by their published experiments.

5. Rectal gonorrhœa can often be detected by suitable examination. In two out of four cases of my own a bacteriological diagnosis was possible.

6. Gonorrhœal arthritis may be a sequela of ophthalmia neonatorum.

7. My experiments on the inoculation of the eyes of newborn rabbits and kittens with gonococci gave negative results.

A CASE OF COLLES'S FRACTURE TREATED PRONE ON A FLAT SPLINT, WITH CHIEF REGARD TO RUPTURED LIGAMENTS.

BY EUGENE R. CORSON, B.S., M.D.,

SAVANNAH, GA.

WHATEVER doubt may have existed as to the true nature of Colles's fracture and the causes of the subsequent deformity in many cases, the *x*-ray has removed. In my paper in the MEDICAL RECORD for May 8, 1897, I attempted to show that the deformity, often following treatment in the best hands, was due to ruptured ligaments rather than to broken bone; and I attempted to map out a line of treatment which looked especially to this view.

I tried to show that in severe cases of Colles's fracture, besides the fracture of the lower end of the radius, be it simply transverse or comminuted, its styloid process was broken off, and with it the styloid process of the ulna; and that the two radio-ulnar ligaments and the strong internal lateral ligament were also ruptured. The other ligaments of the joint must also be more or less affected, but the above-mentioned ones were chiefly concerned in the subsequent deformity. That the rupture of the internal lateral ligament was shown by the falling of the hand to the radial side and by the breaking off of the styloid process of the ulna, so beautifully shown by the *x*-ray.

Since writing that paper I have had a typically severe case of Colles's fracture whose nature and

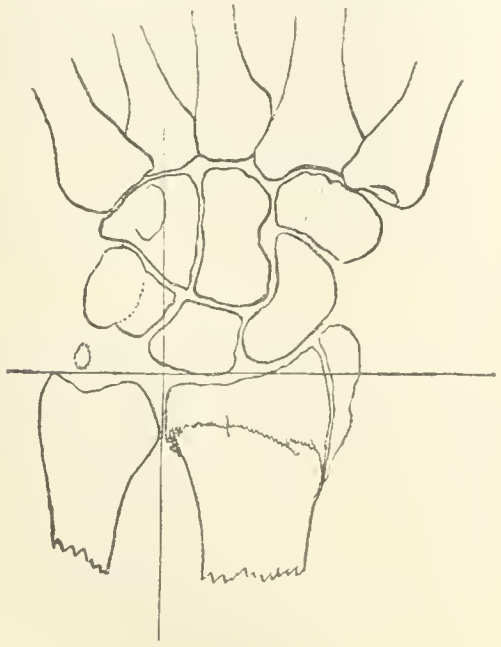

FIG. 1.

course I have carefully studied through the fluoroscope, and whose treatment has been based on the view there set forth. The study of this case has not only emphasized what I then wrote, but has also shown that the treatment is right in principle, even if the details of its carrying out are not all perfected.

A gentleman of thirty-eight fell through a hatchway, sustaining a Colles's fracture. When first seen

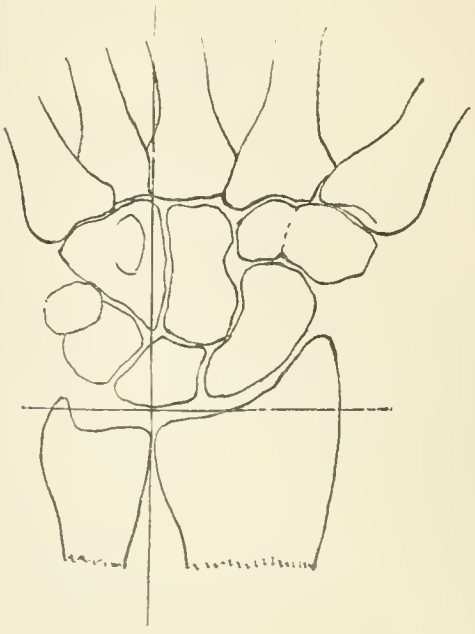

FIG. 2.

the deformity was great, the distal fragment of the radius being displaced dorsally, which gave the characteristic silver-fork deformity, and also the appearance as if both bones were broken. This was remarked by the physician I called in to give the anæsthetic. The patient was very thin and there was only a moderate amount of swelling present. Under chloroform I replaced the broken fragments with ease, and put up the wrist by the method described in my paper. The wrist and forearm were laid prone and in a straight line with each other on a light flat splint, slightly padded, and extending from an inch below the elbow to the metacarpo-phalangeal articulation, thus permitting free movements to the fingers. To overcome the displacement of the ulna toward the palmar surface, a wedge or prop was made of a narrow roller bandage, rolled sufficiently thick to bring the ulna into its natural plane, and long enough to extend well over the pisiform bone, thus bridging the ulno-carpal joint and forming a *point d'appui* for the retaining bandage. I dispensed with the pad over the point of fracture in the radius as there was no tendency to displacement, and the general roller bandage seemed quite sufficient to hold it in place. With a narrow bandage, say one and one-quarter to one and one-half inches wide, I started on the ulnar side over the pad and carried it around under the splint to the radial side, and over the dorsum of the wrist to the point of starting, making two turns; then from the radial side over the dorsum of the hand to the metacarpo-phalangeal joint of the little finger, under the palm to the corresponding joint of the index finger, and finally across the dorsum of the hand diagonally to the point of starting, thus making a figure of eight; and this repeated two or three times. The bandage was then continued up the forearm to the upper end of the splint. This kept the hand in a straight line with the forearm. Thus placed, a straight line through the middle of the index finger will touch the outer edge of the styloid process of the radius; this is a good guide. Towels wrung out of cold water were applied and continued at intervals for a week, alternating with gentle massage. As soon as the patient could get to my office, about thirty-six hours after the injury, the parts

were examined by the fluoroscope through the bandage and splint and found to be in good position. I saw a small fragment of the styloid process of the ulna broken off which I had failed to detect in my manipulations under chloroform, though I had carefully sought for it. It was of course too small to be detected in that way. This proved that the internal lateral ligament was torn loose.

At the end of three weeks I took a careful radiograph of the wrist from which the above outline tracing has been made (Fig. 1). After much thought and experiment I have come to the conclusion that the best way to show the revelations of the *x*-ray in such a case is to trace the outlines carefully on tracing-cloth or paper over the negative by a strong transmitted light, all other light being shut off. For the correctness of this tracing I can vouch, and I think it will show in a very striking way the fractured bones and their relationship to the carpus. It shows the characteristic transverse fracture of the radius as well as its fractured styloid process, both fragments in good position. The little piece torn loose from the styloid process of the ulna is plain enough. In replacing the dislocated ulna it has been perhaps slightly over-replaced and has been separated from the radius more than normally exists, not apparent, however, in examining the wrist. There is evident a slight falling of the hand to the radial side with a certain amount of adduction causing a displacement of the hand of about four millimetres, also apparent on examining the hand and forearm. For comparison I have introduced a similar tracing of a normal wrist, taken, of course, from another subject, as shown in Fig. 2.

The bandage was kept on six weeks, the parts being gently massaged several times daily. I consider this length of time necessary for the restoration of the ruptured ligaments. The movements of the wrist were found to be fair enough; there was a slight thickening over the dorsum of the radius at the point of fracture. I doubt not that three or four months will quite restore the parts to their natural movements. The patient, at any rate, is satisfied with the result.

This treatment is not only simple but it gives the surgeon complete control of the parts for appliccation and massage, and he can watch any slipping of the parts from their original reposition. Moreover, the prone position is the best one for a correct placing of the distal ends of the radius and ulna, the two bones at their ends being farthest apart in pronation. In this position, again, there is the least strain upon the ligaments; it is the most natural position for the forearm and hand when at rest. In this position, further, the distal ends of the ulna and radius are most symmetrically placed to the bones of the carpus, and the carpus and forearm are more nearly in the same plane. Plaster-Paris and the many cumbersome splints figured in our text-books and quite generally used must go. Any splint or bandaging which prevents a constant inspection of the hand and forearm is dangerous, for there is ever a tendency of the hand to fall to the radial side from the ruptured ligaments and the muscular pull, as well as the dorsal displacement of the lower fragments of the radius.

The tendency in the modern treatment of fractures is toward a simpler retaining apparatus as well as a more systematic use of massage, electricity, and passive movements; and certainly the wrist offers the best opportunity for carrying out this principle. A simple transverse fracture of the radius when properly replaced, should this even be necessary, requires the simplest bandage. It is only when the more important ligaments are ruptured that the best judgment and care of the surgeon are brought into play; and now there is added to our resources the magic of the *x*-ray, that dark light which illumines as no other light can.

BACTERIUM COLI COMMUNE (ESCHERICH) IN THE URINE, AND ITS SIGNIFICANCE.

By P. W. NATHAN, M.D.,

CLINICIAN FOR DISEASE OF CHILDREN, [illegible]
FELLOW N.Y.A.M.

Two of the cases to be reported have interesting features aside from the above-mentioned; they are therefore discussed more in detail.

Case I.—Mathilda L——, aged fourteen years, was sent to me by the family physician, with the following history: For a number of years she has been suffering from vertigo. Three years ago the family physician was consulted, and, locating the cause in the naso-pharynx, he sent her to a specialist for treatment. This being of no avail, she was placed upon tonic treatment, with the hope, it was said, that she would outgrow the affection. About six months ago the vertigo became so severe that the patient was compelled to take to her bed. From what I can gather, the symptoms at that time were vertigo with loss of consciousness, severe supra-orbital and infra-orbital neuralgia, and retention of urine. After she had been in bed some two weeks the severity of the attacks of vertigo diminished, and the rentention, after the frequent use of the catheter, ceased. The supra-orbital and infra-orbital neuralgia, however, continued, and it was for this that she was sent to me for treatment.

Family history: Both grandparents died of old age. She has no chronic nervous disease nor is there nervous disease in the family. Mother neurotic; father perfectly well. She has one sister and four brothers, who all had convulsions in infancy; at present they are perfectly well.

Previous history: She has with the exception of measles and whooping-cough never been seriously ill. She nursed as an infant, and was the only one of six children who never had convulsions. A year and a half ago she began to menstruate, and has since then been regular. She did well at school; she worked very hard and always stood well in the class. At home her mother had always found her obedient and congenial, and in no way different from any of the other children.

Status præsens: March 6, 1897, the patient complains of pain over the supra-orbital and infra-orbital foramina. There are frequent but not periodic attacks of vertigo, which apparently have no connection with the ingestion of food or exertion, but are somewhat relieved by the prone position. They are said to come on suddenly without premonition and are accompanied by partial loss of consciousness. She has never, however, fallen in the street or in any public place; on the contrary, she has always found support and is able to call for assistance. The girl is irritable and prone to fits of passion, as the mother says, with very slight provocation or without assignable cause. She is moody, refuses to associate with her relatives and former friends, and, though formerly very particular, she now takes no interest in dress. Her manner is shiftless, and she strongly impresses one as an hysterical individual. Bowels and micturition normal; appetite fair.

Physical examination, head: No signs of degeneration. Pain on very slight pressure over the supra-orbital and infra-orbital foramina. Eyes, ears, nose, and throat, examined by Dr. Borkan, show no abnormality. Lungs, normal. Heart, arrhythmic one beat in ten omitted; otherwise normal. The liver and other abdominal organs show no sign of disease. Blood, leucocytosis. Urine, normal.

Diagnosis: Auto-intoxication. Treatment, resorcin, outdoor exercise, and cold baths. Galvanization of

[1] Read before the San Francisco County Medical Society.

the supra-orbital and infra-orbital nerves. Improvement very slight.

On April 14th, it was said that the patient had passed no urine for over twenty-four hours. There being no distention of the bladder or any other alarming symptoms, I refused to use the catheter, in spite of the solicitude of the mother. When, however, after forty-eight hours she still insisted upon having passed no urine, I used the catheter.

Urine: Quantity, one hundred and fifty cubic centimetres; specific gravity, 1.015: showed no abnormality. Again she was said not to have passed urine in forty-eight hours; the urine passed at the end of that time was also normal.

The symptoms other than the psychical were not influenced by the four days of retention. Thenceforth, however, the mental condition became more and more precarious. She had frequent attacks of what is ordinarily called hysterics and spoke continually of being tired of life, and the like. This condition became progressively more and more difficult to combat, and, as the home influence was such as not to warrant the hope of improvement there, I advised either taking the patient to a hospital or sending her to a sanatorium. The parents not sharing my opinion as to the benefit to be derived from such a course, I withdrew from the management of the case. Another physician was called, the diagnosis incipient melancholia made, and rest cure advised.

I was called again several days later, and it was suggested that the girl be sent to Dr. Robertson's sanatorium at Livermore, to which I agreed. Here she improved both mentally and physically. It was found necessary, however, to take the urine by catheter throughout the three weeks of her stay. She was carefully watched, and I was informed by Dr. Robertson that the quantity of urine was markedly diminished, though it was otherwise normal.

May 22d, she returned from Livermore and was seen the following day. She looked very well; heart beat rhythmical, abdomen tender. Urine by catheter was one hundred and eighty cubic centimetres, cloudy, acid in reaction, and fetid; specific gravity, 1.025. It contained a trace of albumin, red blood corpuscles, and the micrococcus ureæ. Urea was given to promote diuresis; other treatment as before.

May 25th, urine by catheter. Quantity, two hundred cubic centimetres; specific gravity, 1.022; albumin, trace; red blood corpuscles, micrococcus ureæ.

May 26th, she complained of intense pain over the course of the right ureter, radiating to the bladder; abdomen extremely sensitive. Urine by catheter, two hundred and fifty cubic centimetres; red and white blood corpuscles, abundant micrococcus ureæ. The pain over the ureter, the suppression, and the blood in the ureter led me to suspect stone in the pelvis of the kidney or ureter. The pain continued paroxysmally during the night and next morning. I therefore asked Dr. Rosenstein to perform cystoscopy in order to determine positively, if possible, the presence of stone and its exact location. The Kelly cystoscope was used. The patient took the chloroform very badly, and though a clear view of the bladder was obtained it was impossible, through lack of time and the poor surroundings, to pass a catheter into the ureter.

May 28th, the day following the operation, pain was paroxysmal but not so severe. Urine: quantity, five hundred cubic centimetres, cloudy, acid reaction; specific gravity, 1.021: it contained 2.2 gr. of albumin (Esbach), bladder epithelium, red and white blood corpuscles, and was loaded with uric-acid crystals.

Treatment: Urotropine, 1.5 gr. a day, alkaline water: potassium bromide and chloral hydrate per rectum when the pain was severe.

May 30th, the urine was still loaded with uric-acid crystals, but there was a marked diminution in the other abnormal constituents. From now on the pain over the ureter gradually diminished in severity, the quantity of urine increased, and the blood, uric-acid crystals, and other abnormal constituents disappeared. The mental condition on the contrary became more and more difficult to combat. She became hysterical and refractory, a source of constant worry and annoyance to those surrounding her. This condition I had no doubt was in a measure due to the lack of tact upon the part of her relatives, so, when on June 7th the urine was again normal in character, I sent her to the country.

On her return, June 18th, she complained of tenderness over the entire abdomen, so that she could hardly bear the weight of her clothes. There was obstinate constipation, and she still had attacks of vertigo, though these were very much less frequent. Urine normal. She was given aloes, rhubarb, strychnine, and belladonna for the constipation, and the alkaline water and constitutional treatment were continued.

July 27th, I was again called. There were naso-pharyngeal catarrh, pain over the bladder, frequent and painful micturition. Urine cloudy, acid; specific gravity, 1.019; it contained a few flakes of bladder epithelium and the bacterium coli in large numbers. The urine continued to be loaded with the bacteria (which were motile and otherwise characteristic) up to a week ago, when after the bladder was washed six times with a weak solution of creolin (one-half per cent.) they disappeared, only to reappear to-day. The pain over the bladder had, however, disappeared, micturition was very much less painful or frequent, and the mental and other symptoms were now entirely absent.

Case II.—G. M——, aged ten years: family history good. She has never been seriously ill until the first attack of the present illness. She is of an extremely nervous temperament and up to a year ago her mental development had been slow; since then it has been rapid. In November last she was taken suddenly ill with vomiting and constipation. The attack was mild and she soon recovered with but slight treatment. Up to August 5, 1897, she had three more attacks, which were progressively more and more severe. On August 5th she had the attack of greatest severity. While playing in the street she suddenly became nauseated and began to vomit. She was immediately put to bed, where she soon sank into a state of semicollapse. The retching and vomiting became almost continuous. She refused to answer questions and was apparently oblivious to her surroundings.

Physical examination: Pupils contracted; heart beat feeble and rapid; abdomen distended and tympanitic, but not tender. Bacteriological examination of the vomit showed the colon bacillus in pure culture.

Treatment: Lavage of the colon, rectal feeding, stimulation.

During the following two days the condition became more precarious. The pulse could with difficulty be felt at the wrist, the extremities were cool, there were jactitation and continuous retching. Pustules made their appearance upon the tongue and lips, and cultures from these showed the presence of the colon bacillus in far greater number than other micro-organisms. The urine, which had heretofore been normal, on the fifth day looked like grease, contained albumin and the bacterium coli commune in enormous numbers.

Treatment: Chloral hydrate and potassium bromide, sherry, and peptone per rectum; strychnine hypodermically; lavage of the colon.

On the sixth day the vomiting and retching ceased, the urine was perfectly normal, and the child began to improve.

Since then she has had three attacks, each one milder and shorter than the preceding. In none of these has the colon bacillus again appeared in the urine.

The administration of resorcin and lavage of the colon between the attacks and the administration of chloral and bromide as soon as the attacks began, I think, did much to mitigate their severity.

Case III.—S. W——, girl, aged nine years. Previous history: Though always delicate she has except for measles never been seriously sick. For some time she has been suffering from vertigo. She recently passed a large number of ascarides lumbricoides in the stool.

Status præsens: Complains of pain upon urination and inability to retain urine.

Physical examination: Otitis media chronica. No other abnormality. Urine cloudy, acid, and of fetid odor; specific gravity, 1.015; loaded with the bacterium coli commune (Escherich).

She was given santonin and castor oil, and passed a very large number of the ascarides. She was then put upon salol, three decigrams thrice daily, and after two weeks was discharged cured.

Case IV.—P. A——, girl, aged one year and nine months. Previous health good. For the last two weeks she cries upon urination. Urinates very frequently and only in small quantity. No other abnormality. Urine cloudy, acid, fetid; specific gravity, 1.016; large numbers of the bacterium coli commune.

Treatment: Salol, 0.2 thrice daily: lavage of the bladder with one-half-per-cent. creolin solution. One week later she was discharged cured.

That the bacterium coli commune (Escherich) which inhabits the normal human intestine can under certain conditions, or when it invades other organs, become pathognomonic, has been proven beyond question. Recent investigations[1] have shown it to be the most frequent and most important etiological factor in the gastro-enteric diseases of children,[2] in fact it has been found in connection with inflammatory processes of nearly all the organs.[3]

Interesting as it would be, it would lead too far were I to discuss even superficially its morbid influence in the many affections with which it has been found associated. I must therefore confine myself to the discussion of its causal influences in the cases presented.

Since Krogius (1891)[4] found the bacillus pyocyaneus of Albarran and Hallé and the bacillus septicum of Clados identical with the colon bacillus, the investigations and experience of many authors have shown the colon bacillus to be the most frequent cause of cystitis, pyelitis, and pyelo-nephritis. Savor[5] reports seventeen cases of ascending nephritis, in ten of which he found the colon bacillus in pure culture, and in three associated with the proteus of Hauser. Von Wunscheim[6] found it in pure culture in eleven out of sixteen cases.

In my cases it is plain that the colon bacillus played at least a very important part in bringing about the disease; in two of the cases it was certainly the direct cause (Cases III. and IV.). Its presence in pure culture in the urine and vomit in one of the cases, and its presence in the urine in the others, and the rapid improvement which followed its disappearance, make this almost certain.

In the early records of Case I. it is noted that the micrococcus ureæ was found. At that time I had not the bacillus coli in mind, and did not examine the organisms thus named very closely. Now, after close observation I have no doubt that these organisms which appeared spherical were colon bacilli in rapid motion, which gave them this circular appearance. At any rate, no organism was found until the patient returned from Livermore, and I see no reason to believe that they were not the same then as they were afterward, especially as there was no record of ammoniacal urine.

The diagnosis of auto-intoxication in this case was based upon the arrhythmic heart action, vertigo, neuralgia, coincident with leucocytosis, which are symptomatic of poisoning by the xanthin bodies. Later, when to these symptoms were added hypochondria, hysterical manifestations, pain over the ureter, blood and uric-acid crystals in the urine, and retention, the case became typical of the condition known as uric-acid diathesis. Finally, the blood and severe pain suggested the presence of stone either in the pelvis of the kidney or in the ureter.

Here a word of explanation is perhaps necessary. Formerly uric acid was supposed to be a product of the general albumin metabolism and an intermediate stage in the formation of urea. Since the researches of Beneke (1874) this theory has been considered untenable, and has been for the most part abandoned. The researches of Hertraczewski and Kossel have shown that the uric acid is the end product of nuclein: moreover that the so-called xanthin bodies are intermediate stages in the uric-acid formation. Recently Hertraczewski has shown that the destruction of nucleated cells, especially white blood corpuscles, within the body causes a perceptible increase in the amount of uric acid excreted. In leukæmia he found the amount of uric acid to increase in ratio to the increase of leucocytes, and Dunnin and Norbaczek found the same to be true in the resolution stage of croupous pneumonia, when, as is known, large numbers of leucocytes are destroyed. When the xanthin bodies are not completely oxidized they are not readily eliminated, and circulate within the body, causing intoxication or, as it is called, auto-intoxication. Experiments with these substances upon animals produce symptoms closely allied to such diseases as rheumatism, gout, lithiasis, etc., and these diseases are considered by many to be of this nature.

We have in our case signs and evidences analogous to those caused by poisoning by the xanthin bases, or auto-intoxication. We find on the other hand at various stages of the disease the colon bacillus present in the urine. Have we here two separate and distinct morbid conditions, coincident but not dependent. Are they interdependent, or does one cause the other? The question is difficult to decide. On theoretic grounds it might be supposed that there was primary infection from the colon bacillus, that this organism interfered with the function of the kidneys, and considering, as some authors do, the kidney as the seat of the uric-acid formation, that there were incomplete oxidation and auto-intoxication by the xanthin bodies. This, aside from the fact that the action of the kidney in the uric-acid formation is still hypothetical, is from the history of the case improbable. The facts that the characteristic symptoms of auto-intoxication were present long before anything abnormal was found in the urine, and that the colon bacillus appeared only after frequent catherization, the usual cause of infection, point to this as a secondary affair.

Charrin and Bouchard[7] found the bacillus not infrequently present in the male urethra and in the vulva, and they as well as others state that the bacillus is usually carried into the bladder with the catheter or sound. In this case there was catarrhal vaginitis, and the mucus from the vagina gave a pure culture of colon bacilli. It seems therefore only reasonable to consider the catheter the cause of infection.

In the other cases infection cannot readily be traced to this source. In Case II. the catheter was never used, and cultures from the vulva and vagina never showed any colon bacilli. Here as in the other two cases the bacillus must have entered the bladder directly by penetrating either the intestine or rectum. That it can penetrate the intestine has been shown by a number of investigators. Redet and Roux found it in a large number of cases of peritonitis of intestinal origin, in many of which the bacillus must have pene-

trated the intestinal wall. Wreden[8] by experiment found that it can gain entrance directly from the rectum to the bladder when the rectal mucous membrane is injured. Posner and Lewin[9] bloodlessly occluded the rectum and simultaneously tied the urethra in animals; the result was the appearance of the colon bacillus in the urine and the development of cystitis. The bacillus in these experiments did not in all probability directly invade the bladder, for when the bacillus prodigiosus was injected into the intestine under similar conditions it was found not alone in the kidney and urine but also in the blood and bile.

Case II. seems to me analogous to the three experiments. The sudden onset of the symptoms, the absence of indigestion, constipation, and diarrhœa previous to the attack, the persistent vomiting and collapse, indicate some poisoning or intoxication. It would not, judging from the frequent repetition of the attacks and from the relief obtained by the sedatives and high irrigation, be difficult to ascribe the disease to volvulus, which by partly occluding the intestine allowed the toxins of the no doubt virulent colon bacillus to be absorbed, or cause, as was undoubtedly the case, general infection. Of course this must remain problematical; still in my opinion this is the nearest approach to a positive diagnosis. That general infection took place is proved by the bacilli found in pustules on the tongue and lips, and that they passed into the urine from the blood is proved by their disappearance from it when the other symptoms disappeared.

In Case III. a condition of greater permeability of the intestine was probably caused by the irritation of the ascarides, and the bacillus in this case probably took the direct route to the bladder.

In Case IV. the method of invasion must remain doubtful.

Of late, cystitis due to auto-infection by the bacterium coli commune of Escherich has been found quite common in children, especially in girls. Escherich first called attention to this disease by a report of four cases. Subsequently numerous cases were reported, and it is now beginning to find a place in the newer text-books on pædiatrics. Trumpp, in the last volume of the *Archiv für Kinderheilkunde*, reports thirteen cases, nine in girls and four in boys, which occurred in the hospital during an epidemic of enteritis.

Roberts, Reinhold, Ross, and Shottellius have published cases in which large numbers of colon bacilli were found in the urine, there being no other abnormality at the time of urination. According to Krogius[4] the urine is always acid, cloudy in appearance, and has a fetid odor. He has in a number of cases found it to exist without other symptoms. However, that in many cases it does cause cystitis is proved by the numerous instances reported by Escherich, Trumpp, Scherich, and others, and I think by the cases presented this evening.

SCARLET FEVER A LOCAL DISEASE.

By LUKE FLEMING, M.D.,

TARRYTOWN, N. Y.

Scarlet fever is a self-limited, acute, infectious, local disease of the throat, presenting marked general symptoms. If I may be permitted to use this definition as a text and to claim for it originality, I probably shall be assailed by many, on the ground that in it there is nothing new. Still there is one part of it which I believe to be new and which I wish to emphasize, and that is that scarlet fever is a local disease of the throat. Furthermore, I hold that the commonly accepted teaching that the desquamated skin is the source of the germ, and in consequence that the desquamatory period is most dangerous, is wrong. Scarlet fever is the twin sister of diphtheria. They bear to each other in all the important features a close resemblance. Both attack the mucous membranes of the throat, especially of children. Both have a tendency to invade the nares and trachea, and both likewise produce false membrane. This production, however, is strong in diphtheria, and the resulting membrane is thick and gray, while in scarlet fever the production is weak and the membrane is thin and brown. Both, too, produce poisons similar in their destructive action upon the blood corpuscles, as is seen in those cases presenting hæmorrhagica purpura, and popularly known as "black scarlet fever" and "black diphtheria." In scarlet fever, however, the poison exercises a most marked irritative power on the organs by which it is excreted; if by the bowels, we get diarrhœa; by the kidneys, nephritis; and by the skin, dermatitis. The poison of diphtheria, on the contrary, is more akin in its action to aconite, paralyzing nerve tissue.

Now, diphtheria has for a long time been recognized as a distinctly local disease. Certainly no one thinks of looking in the skin, the urine, or the fæces for the Klebs-Loeffler bacillus. But scarlet fever has not received this recognition. It is called a constitutional disease, and we are presented with a spectacle somewhat unique, it seems to me, of men searching diligently in the cutaneous and urinary excretions for the bacillus of scarlet fever. Eckland describes what he holds to be the specific microbe found in the urine, and Edington another in the skin. A germ capable of producing the lesions of scarlet fever in passing through the system to reach skin and kidney would produce a general septicæmia from which few if any would recover. For instance, a woman sick with scarlet fever is delivered of a child. Would she develop puerperal fever? I think most men will answer that if proper asepsis is practised in her accouchement she will not. But if the scarlet fever germ is in the blood, she could not possibly escape it. Now if the germ is in the skin, it must get there through the general circulation, and that it is in the skin every text-book teaches. "The contagion of scarlet fever is probably not developed until the eruption appears and is particularly to be dreaded during desquamation."[1] "It is generally conceded that a scarlet-fever patient is most dangerous during the stage of desquamation, and that the branny scales of this period are the most frequent carriers of the contagion, though others claim like properties for the mucus, urine, and fæces."[2] I am inclined to question the truth of such statements. In my humble opinion neither skin, urine, nor fæces contains the germ except by accident; in the tissues of the throat this germ finds its first home and last resting-place, and it does not exhibit, as some would have us believe, a tendency "to wander away from its own fireside."

In scarlet fever the only constant lesion is a sore

[1] Osler: "Theory and Practice," p. 67.

[2] Starr: "American Text-Book of the Diseases of Children," p. 156.

throat. In eighty-eight cases seen recently at the Willard Parker Hospital, through the courtesy of the house staff, there was disease of the throat in all, varying in intensity from a mild inflammation to severe involvement of all the neighboring cervical tissues. In one there was a nasal discharge, as though the seat of the infection lay in the nose. As a general rule, the severity of the general symptoms in scarlet fever is in direct proportion to the severity of the local lesion in the throat. It may sometimes happen, however, that a child of weak resisting power will succumb quickly to the poison of an infection which in a clinical aspect is mild, and which in another child, of strong resisting power, would create only mild general symptoms. The condition of the throat is of the highest import in scarlet fever, and the most pronounced symptom, the rash, is of more importance in a prognostic than in a diagnostic sense. We can have a severe scarlet fever without a rash. Indeed, while a severe rash is indicative of a severe infection, it is not indicative of danger. But a severe sore throat and no rash are cause for the greatest alarm. To understand the value of the rash, we must start right by recognizing that scarlet fever is a disease of the throat, caused by a specific germ which produces a specific poison; and this poison, being absorbed into the circulation, must be excreted. A rash indicates that this poison is being excreted by the skin, whereas no rash indicates that it is being excreted by other organs, usually the kidneys. Now a poison capable of producing a dermatitis, such as we see in scarlet fever, is very severe in its action on the kidneys, and a severe rash therefore is a favorable symptom, because it tells us that the burden of this excretion is being done by the skin.

In view of this fact it is incomprehensible to me how any one can recommend a cold pack in the treatment of scarlet fever. It is claimed that by the consequent reduction of temperature the patient is relieved—insomnia, nervousness, etc., are overcome. It strikes me, however, that this little good is badly compensated by the dangers incurred. Cold applied to the surface of the body must certainly constrict the cutaneous blood-vessels, and thus throw suddenly and severely the volume of blood, and therefore the volume of work, upon the kidneys. Considering the fact that a high temperature is due to the presence of toxins, the rational plan of treatment for a high temperature is a hot pack.

There is no disease that responds more promptly to a good plan of treatment than does scarlet fever, and in this plan there are two cardinal rules. One is to practise disinfection at the seat of disease, and the second to protect the kidneys at the expense of the skin. In regard to the first of these rules, I do not mean that the nurse should be armed with a spray and a solution of peroxide of hydrogen. The spray is the most deadly instrument that has been placed in the armamentarium of the physician. It is responsible for the past high mortality in diphtheria, and I do not wish that it should exert its baneful influence on our little scarlet-fever patients also. But what I would suggest is that suitable mild antiseptic mixtures be given, either as douches or in teaspoonful doses as internal medicine, to be by the act of swallowing brought in contact with the diseased surface, and that proper care be given to nasal and buccal hygiene.

There are some, no doubt, who will scoff at local treatment of scarlet fever, claiming, as they do in diphtheria, that it is ineffective. I, however, believe that both scarlet fever and diphtheria are specific infected wounds of the throat, and that he who treats them locally on antiseptic principles is merely carrying out the idea and teachings of Lister. To those, however, who are wedded with a blind love to the serum treatment of disease, I would respectfully suggest that they look for the specific germ of scarlet fever in the throat, and abandon the idea that it teems in the skin; that instead of the desquamatory period being the most dangerous, a scarlet-fever patient is dangerous only while a diseased throat is capable of producing an infectious mucus. This suggestion may savor somewhat of assurance; but it oftentimes happens that some men, from constant application to the microscope, are unable to see things with the broad range of the naked eye. They feel that everything microscopical must be supported, whether it be inoculation for mythical hydrophobia or an impractical Widal reaction. For us all it might be well to remember that common sense is always a good friend to truth, and that wisdom is not always an attribute of the wise. We cannot well forget how the plain, poor sailor of Genoa proved to the wise men of his time how flat was the world and how wise these wise men were.

HOW TO PREVENT TYPHOID FEVER IN RURAL DISTRICTS.[1]

By HARVEY B. BASHORE, M.D.,

WEST FAIRVIEW, PA.

Typhoid fever is the plague of the country districts. In a certain locality in Michigan where accurate statistics were kept it was found that in an area in which the people used well water there were just twenty-six times as many cases in proportion as there were in a city district all of whose inhabitants used a Lake Superior water. In Pennsylvania I think that the average is fully as high, at least it would reach ten to fifteen times more for the country than for the cities.

There is no longer a question that the prevalence of this rural typhoid arises from the fact that the population depends upon polluted well water, and that the wells are infected from privies which one time or another have held typhoid excreta and infected the surrounding ground water.

Wells might not be so bad were it not for the fact that the ground water infected with typhoid purifies very slowly.

To eliminate this disease it is plain that we have to eliminate one or the other means of infection, either the well or the privy vaults which have poisoned the waters.

It will be a hard and thankless task to get people to give up their privy vaults and use earth closets, and it will be a matter of many years' teaching before they do it.

On the other hand, changing the water supply is comparatively easy, and meets with more general approval. A good many of the small villages are already working in this direction by attempting to procure a public supply from some neighboring spring, and by this means they hope to meet the difficulty; but a public supply, such as is generally furnished to small towns, very often becomes polluted, and the danger is worse than ever. Then, too, a public supply is comparatively costly.

There is another way, however, to bridge the difficulty successfully and cheaply, and that is by substituting cisterns for the old wells. By this means typhoid fever may be eliminated more quickly and more thoroughly from rural districts than by any other method.

The problem of using cistern water has been carefully studied, and we are able to tell just exactly the size of the cistern, the amount of collecting surface,

[1] Read by title at the Philadelphia meeting of the American Public Health Association.

etc., necessary for any given family, calculated for the known rainfall of the district. For example, if the roof surface contains one thousand square feet and if the rainfall is thirty-seven inches, about twenty thousand gallons will be collectable annually, which at ten gallons a head daily is more than sufficient for the wants of an ordinary family. For a yearly yield of this amount the cistern need not be excessively large, for the rain does not all come down at once. A cistern five feet deep and ten feet in diameter will hold about two thousand gallons. This will probably last more than a month, and before it is exhausted there will likely be more rain to add to the supply, for it is rare that a month passes without some precipitation.

If we rely on the cistern to eliminate typhoid fever, we must pay some attention to its construction, for only on its ability to keep out soil water rests the superiority of the cistern over the well. If carefully made of bricks and thoroughly cemented, it will be proof in most cases against this contamination from the soil. I know personally of such a cistern which was made twenty-five years ago and is still as good as ever.

Cistern water generally has a peculiar flavor arising from the decomposition of vegetable materials which get into the water from the collecting surface. This may be avoided in a great measure by keeping the cistern clean and by a "cutoff," so arranged that the first washings from the roof are turned into the street; or if thought necessary the water may be filtered.

In order to filter cistern water all we have to do is to build a partition in the cistern, with several holes at the bottom, connecting the two sides. Into the one side is placed the filter, consisting simply of three or four feet of coarse sand or of layers of gravel, polarite, and sand. Into this side the roof leader empties and into the other dips the pump. By this means cistern water may be made as palatable as any other water, and obtained at much less expense.

That the use of cistern water will prevent typhoid fever in rural districts is not hypothetical, but a fact proved by experience. In a certain county in Pennsylvania, on account of an underlying limestone formation, there is a great inability to get good well water, and as a consequence the greater part of the community uses cisterns. In this region a careful study of the records of the resident physicians has been made, and it was found that there was a marked absence of typhoid fever. One of the towns in this place, well known to the author, will serve as an example of all the rest. This town of twenty-two hundred inhabitants has for many years depended almost exclusively on cistern water, and as a result typhoid fever is practically an unknown disease. In the last twenty years, so the oldest resident physician tells me, there has not occurred one case of typhoid fever among those exclusively using cistern water. In all this time, moreover, there have been very few cases of fever in the whole town, and every one has been traced to the use of well or spring water. The exact record for the last five years is three cases of fever, which the attending physician would not call "true" typhoid. Taking these cases, however, to be typhoid, and counting one death for every twenty sick, it would make the death rate of this community something like one per ten thousand—probably the lowest, at least one of the lowest, typhoid death rates ever attained.

Here, then, is a town where the typhoid sick rate is hardly worth considering and where the death rate is almost *nil*.

If all rural dwellers would give up their wells and resort to the cistern, the story of this one town would be repeated everywhere and rural typhoid would become an unknown disease.

Progress of Medical Science.

The Quantity of Ammonia Contained in the Human Blood under Physiological and Pathological Conditions.—Dr. H. Winterberg (*Wiener klin. Wochenschrift*, 1897, No. 14), basing his conclusions upon an examination of the blood of twelve healthy persons, states that the average quantity of ammonia in the circulation is 0.96 mgm. in each 100 c.c. of blood, this quantity varying slightly in each individual, as do the salts, etc. The quantity varies greatly in fever; it is usually increased, but may be unaltered or diminished. More important are his observations of the uræmic state, in which he noticed but a slight increase in the ammonia, once up to 2 mgm., once to 1.4 mgm. The blood of a dog after extirpation of both kidneys showed no change in the amount of ammonia. This experiment he thinks tends to prove the fallacy of Frerichs' theory that uræmia is due to an accumulation of carbonate of ammonium in the blood.

Botryo-Mycosis Occurring in Man.—For several years Drs. A. Poncet and L. Dor (Lyons, France) have been observing an apparently inflammatory or rather neoplastic growth, which in its location and anatomical construction is different from other tumors. In four such instances reported, the disease was located twice on the finger, once on the thenar eminence, and once on the shoulder. It is described as an ulcerated fungoid mass of from pea to nut size, originating in the cutis, resembling a mass of granulation tissue, rich in blood-vessels and attached to the underlying tissue by a pedicle, the whole giving one the impression of a fungus growth. This papilloma consists histologically of an inflammatory structure, with more or less thick fibrous stroma, in which the botryomyces are distinguishable, and hence the disease is really a botryomycosis, a disease already known to occur in horses after castration. The fungus was recognized microscopically and by culture, and finally when a similar growth was produced by the inoculation of an ass. In all four cases there was but a single pediculated, painless, vascular tumor. From this it would seem that botryo-mycosis is a distinct disease, to which man is susceptible.—*Therapeutische Wochenschrift.*

The Syndrome of Chronic Arthritis Deformans.—Dr. F. Barjon (*Gazette des Hôpitaux*, August 28, 1897) concludes a paper with the above title as follows: "1. Debility, predisposition, and heredity, together with various pathogenic influences, develop rheumatism; either acute articular rheumatism or pseudo-rheumatism, such as that resulting from the different infectious diseases—gonorrhœa, scarlatina, tuberculosis, diphtheria, etc. In any case it does not seem to depend upon a primitive lesion of the nerve centres. 2. In these diverse chronic manifestations there is a clinical syndrome, always the same, evolving three periods—articular, neurotrophic, and myelopathic—always accompanied by essentially the same anatomical lesions of the articulations and bony extremities, and having constantly the same urosemeiographic curve. 3. The distinction actually established between the affection called "true rheumatism" and the "pseudo-rheumatism" should be considered as provisory. It is destined to disappear with the more accurate determination of the causes of each rheumatic process and the conditions which vary the ulterior evolution of this same process. 4. The *x*-rays may be very useful in differentiating anatomical lesions created by the chronic rheumatismal syndrome and those of other deforming joint diseases, such as gout and nervous affections."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 15, 1898.

THE GOVERNOR'S MESSAGE AND THE PAUPER INSANE.

THE message of the governor of New York to the State legislature contains many pertinent and suggestive facts relating to the proper dispensation of public moneys for charitable purposes. On the whole, his arguments against undue extravagance in the care of our paupers are well founded, and his recommendations of remedies for their abuse are eminently reasonable. When we learn that there are nearly seventy thousand sick and poor who are obtaining State aid, and that the enormous sum of $20,000,000 is necessary to that end, the question of adequate distribution of such a sum becomes a matter for serious consideration: especially must this be apparent when fully $5,000,000 of this amount is appropriated for the custody and treatment of the insane.

Much has been said and written concerning the care of the pauper lunatic, and on general principles it is a matter for congratulation that all such patients are now the wards of the State. In the interests of ordinary humanity, and with the instincts of a laudable charity, it is always a sacred responsibility to help and guard the weaker brother. Generally, however, it is not so much a question as to whether enough is not done, as it is that too much is attempted. It strikes us that His Excellency, while endeavoring to check undue extravagance, is eminently just in being conservatively charitable. His opinion regarding the actual needs of our insane paupers will doubtless meet with the responsive indorsement of every one conversant with the condition of affairs to which he refers.

It cannot be denied that our State hospitals for the insane are very expensive affairs. The buildings have a palatial magnificence out of all proportion to their actual needs as strictly hospital establishments. Millions of dollars have been spent in the erection of these plants without in any ostensible way affecting the real ends for their construction. Generally speaking, there is more building than hospital, more show of luxurious surroundings than there are treatment and cure of patients.

On this latter point the governor very pertinently remarks: "A pauper is not, because of his insanity, entitled to extravagant fare or gorgeous surroundings. The large majority of farmers and mechanics live in the humblest way and contribute by tax to the support of State institutions. Justice to them will not permit, and humanity to the insane does not require, that lavish and ill-considered outlay which characterizes the quarters holding some of the State's insane."

Very properly he enjoins upon the managers of such institutions "the constant recollection that the expenses of these inmates are paid by many thousands on the outside whose surroundings are far less comfortable."

Considering the needs of some of the asylums around Greater New York, he is very reasonably of the opinion that "there are two extremes in this State in the care of the insane. One is so extravagant and the other so poor that both deserve censure. The State is paying every dollar it ought for its pauper insane Money enough has been expended to provide comfortable quarters for every inmate, but waste in some places and neglect in others have produced the extremes I describe. The first cannot be corrected, for the outlay is made; but the last can and ought to be without delay. All the money to be paid out for new buildings should be devoted for some time to come to the institutions around New York City, and the amount thus expended should be increased to the utmost limit by keeping the expenses of other institutions now well provided for down to the smallest figure. Whatever structures are built should be comfortable and substantial, nothing more; and the practice of erecting palaces at the public expense for the accommodation of paupers has, I hope, seen its last example." To all of which we heartily say, Amen.

THE COUNTY SOCIETY AND THE HEALTH BOARD.

IT is many years since a president of the Medical Society of the County of New York has appreciated his duty to the profession so fully as the present incumbent. Dr. Jacobus, in his inaugural address, called attention to many of the disabilities under which the profession is laboring, and suggested the proper remedies—namely, thorough investigation of alleged evils by competent committees, with instructions to devise and recommend suitable legislation. One of these committees was charged with an investigation of the relations of the health department to the profession and the public: and its report, adopted unanimously at the last meeting of the society, represents the careful work of men whose intelligence and constant devotion to the interests of the profession for over twenty-five years are known to all. The bill prepared by them, and which has been presented to the legislature with a promptness that other committees might emulate, now awaits the action of our lawgivers. We have examined its provisions with care, and find that, while it in nowise interferes with the present *personnel* of this department, it rescinds the antiquated provision that prevented a physician from being the presiding officer. It defines the duties of physicians in regard

to the report of cases of contagious and infectious diseases, and specifically names the ones that shall be reported. It provides against the further increase of hospitals to be controlled by the board, and absolutely repeals the obnoxious section which virtually made every physician employed in the department a spy on his fellow-practitioner. The present charter authorizes the department to manufacture an indefinite number of antitoxins. This power has been materially curtailed, and its authority to offer them for sale in competition with private producers is absolutely repealed. These are the principal changes, and we believe they reflect the sober and thinking sense of the profession. It is to be hoped that no obstructions will be thrown in the way of prompt and favorable action by the legislature. The presentation of this bill, however, does not terminate the work of the committee, which will be continued by Drs. Hadden, A. H. Smith, Piffard, and Satterthwaite.

THE WRECK OF A LIFE AND ITS WARNING.

The sudden and lamentable death of a young physician of this city on the morning of January 1st, from an overdose of cocaine, was a sad termination of a career which had the promise of being highly prosperous and even brilliant. The doctor, after completing his medical studies at the College of Physicians and Surgeons, nearly eight years ago, and serving as interne and house physician at several of the city hospitals with distinguished ability, had entered upon the private practice of his profession with unusually bright prospects of success. But, unfortunately and unadvisedly, he several years ago commenced the habitual use of cocaine in a medicated spray for the relief of a chronic nasal catarrh from which he had long suffered. As is quite sure to happen in such cases, the dose which at first afforded relief soon required to be increased in order to produce the desired effect; and then a demand for the drug in gradually increasing quantities, as a general stimulant, was created; until finally, a dose somewhat too large, or taken when the systemic powers of resistance were below the usual standard, led to a fatal result.

There can be little doubt that practitioners of medicine often fail in their duty in prescribing stimulants and narcotics to be used habitually as remedies in chronic disease, or in not clearly and emphatically directing that these remedies are to be used only as temporary expedients, which must on no account be continued after the initial prescription has been exhausted—at least without further advice and a renewed prescription. And it may be added that the use of stimulants and narcotics in chronic diseases is not simply dangerous; in most cases the practice involves a medical blunder, since it serves to weaken the parts it was intended to strengthen, and so to perpetuate the maladies it was intended to cure.

Silver-Nitrate Stains can be removed by rubbing with a cloth wet in one part each of corrosive sublimate and ammonium chloride to eight parts of water.

THE SANITARY CONDITION OF THE ARMY.

According to the report of the surgeon-general the sanitary condition of our soldiers is on the whole satisfactory. The new quarters at posts recently built are stated to be excellent from a sanitary point of view. At some of the old posts the buildings are said to be more or less out of repair, overcrowded, with inadequate ventilation and primitive methods for the removal of wastes. Nevertheless it is pleasing to note that there is a steady improvement in hygienic conditions all along the line. The water supply at a few of the posts is made the subject of complaint, but in the majority of instances little fault can be found in this respect. The fact is pointed out that there is a well-marked coincidence between the prevalence of fever and the amount of field service performed by the troops forming the garrison. Post surgeons in referring to the causation of low fevers in their commands have frequently taken occasion to explain that these did not originate in insanitary conditions at the post, but were incurred by the men when absent on field service. Dr. Smart suggests as a remedy for this state of affairs the use of portable filters for troops when in the field. The question of employing means to insure a purer milk supply is raised at several of the posts, and, as these are for the most part located in country districts, such a proposition cannot be regarded as unnecessary. The time is surely ripe for a radical change to be made in the methods at present in use in regard to dairy supervision in the rural parts of the country. The experiment as to whether the five days' rations when spread over a period of ten days would be sufficient to keep men in proper health, was put to a practical test in April of last year. The result of this experiment went to show that although there was a loss of weight on an average of 2.935 pounds per man, yet that all the forty-six men who composed the troop were at the termination of the march in fine physical condition.

ENDEMIC TYPHOID.

The most frequent cause of typhoid is undoubtedly infected water; the next most common vehicle for spreading the disease is milk. Reference was made in the Medical Record of December 11th to the epidemic of typhoid fever traced to infected milk at Paterson, N. J., and there have also been within recent years many examples in this country in which the disease has originated from similar sources. The origin of endemic typhoid fever is, however, in too many instances shrouded in obscurity, and so long as a case crops up only here and there in a district no very strenuous efforts are made to solve the difficulty. In the course of this past summer typhoid fever in a sporadic form has been prevalent in an outlying portion of Southampton, Long Island, and the residents wisely appointed a committee to investigate the cause. The report summarizing the results of the committee's inquiry has been published, and provides some instructive reading. During the summer of 1897 ten cases of typhoid occurred in a suburb called the Art Village,

a short distance from Southampton, nine of which developed in the place itself. The fact has also been ascertained from two local physicians, that for the last three or four years a number of cases have continuously occurred in the same locality. When it is explained that the district in question is beyond the limit of the Southampton water works, and that in consequence the inhabitants are compelled to depend upon wells for their water supply, it will be understood that the origin of the outbreak was not far to seek. Much attention has of late been paid to the question of the diffusion of sporadic typhoid by means of wells, and particularly in regard to the length of time that the typhoid bacilli will live in these contaminated receptacles. Up to a short time ago Murchison's theory, that typhoid arises from pythogenic causes, was generally accepted. Recently, in the face of the numerous water-borne epidemics, this explanation has been felt not to be altogether satisfactory. The investigations of Sir Richard Thorne on the etiology of endemic typhoid have demonstrated to what an extent the typhoid organism may spread; and have likewise thrown much light on the vexed point as to the duration of life of the bacilli in the soil. Dr. Sidney Martin found, after sterilizing two samples of soil (one of which was saturated with organic matter) and inoculating both with typhoid bacilli, that the organism survived at least two hundred and twenty days in the soil containing much organic matter, while it was dying out of the other in twenty-three days. Dr. Robertson's experiments on unsterilized earth much contaminated with refuse showed that the bacilli died down in the winter, only to multiply freely in the summer.

In connection with these statements *The Hospital* says: "We seem here to see an explanation of the origin of endemic typhoid which fits in with all the facts. When typhoid is imported into a place with clean surroundings and a clean soil, however virulent it may be, it soon dies out. Where, on the other hand, the soil is polluted with decomposing organic and especially animal matter, the typhoid organism takes root, and not only grows but persists, so that whenever the temperature rises to the proper heat and the soil is moistened to the proper degree a great development of the typhoid bacilli takes place; and these, washed into wells or streams from which drinking-water is drawn, again gain access to man, and thus at last give rise to cases of typhoid fever, the origin of which no one can trace, so long is it since the infection was planted in the soil."

Whether this theory is the correct one will require further proof before it will be universally accepted, but at least it sounds plausible. The fact, however, remains, that periodic and frequent examination, both bacteriological and chemical, of drinking-water should be insisted upon, for, while these measures cannot be depended upon to determine with certainty whether a water be dangerous to health or not, yet both are good indices. This course of procedure should be especially followed where the supply of water is procured from wells. The source of the water should be examined with the greatest minuteness, so as to make certain that there is no chance of contamination. Wells, unless properly protected, should be closed. It is absurd, as well as in a high degree a menace to health, that excrement should be placed in one pervious hole and drinking-water taken from another but a short distance away.

It is worthy of notice that although there are disastrous epidemics now, yet endemic typhoid has greatly decreased and the total mortality has immensely declined. This mortality might with care be reduced to a minimum. So far as the Art Village on Long Island is concerned, the remedy for the existing state of affairs surely lies in the hands of the authorities at Southampton. The wells should be abolished, and the Art Village should be connected with the water system of Southampton with all possible dispatch.

News of the Week.

The Wonders of Science.—The new year has opened well as regards medical progress, the first week bringing the news of two astounding discoveries. One of these comes from Mexico and is to the effect that an American physician has lighted upon an herb of such marvellous healing virtues that a few doses of it suffice to put an end at once to the most desperate cases of malarial, typhus, or typhoid fevers. The other, a life-making rather than life-saving discovery, is reported from Vienna. It is said that a Dr. Schenck, a university professor and president of the embryological society, has found out the secret of sex. He finds that this depends wholly upon the nature of the food consumed by the parents, whether one or both the report does not state, and he has proved his theory by a long series of experiments beginning with oysters and ending with man. We may add that we are indebted for these startling details to the daily press, our correspondents in Mexico and Vienna having strangely failed to telegraph us an account of the astounding discoveries.

Randall's Island Alumni Association.—There will be a meeting at the Academy of Medicine on Tuesday evening, January 18th, for the purpose of forming an association of the alumni of Randall's Island Hospital. All who have at any time served on the staff are requested to be present.

The Boston Medical Society.—A meeting of the Boston Medical Society was held on January 1, 1898. The subject of medical abuses in the hospitals and dispensaries was discussed by Drs. S. Goodman, F. F. Whittier, N. M. Goodman, Gustavus Liebman, F. J. Kelleher, Philip Sosnowsky, A. Rovinsky. Papers on the same subject were read by Drs. R. K. Noyes, Charles F. Parker, M Gerstein, the latter dwelling on the abuses in the lying-in hospitals. A committee of five was appointed to report at the next meeting some ways and means to ameliorate the condition of affairs in the dispensaries and out-patient departments. Dr. M. Gerstein presented a bill to be introduced in the coming legislature; it was referred to the committee on medical abuses. The following officers were

elected for the ensuing year: Dr. Samuel Goodman, *President;* Dr. Rufus K. Noyes, *First Vice-President;* Dr. Francis J. Kelleher, *Second Vice-President;* Dr. Morris Gerstein, *Secretary;* Dr. Victor Bychower, *Treasurer;* Drs. N. M. Goodman, A. Rovinsky, Charles F. Parker, J. J. Hanley, B. L. Bernard, H. P. Leonard, *Directors.*

An Example for Future International Congress Committees.—The committee whose duty it is to prepare for publication the Transactions of the Twelfth International Congress, held in Moscow, has been so unusually expeditious that a considerable part of the material is already in the hands of the printer. The Russians evidently believe more in the value of time than did their predecessors of the Berlin and Rome congresses.

Dr. R. Harvey Reed, formerly editor of the *Columbus Medical Journal,* has accepted the position of superintendent and surgeon-in-charge of the Wyoming General Hospital at Rock Springs, Wyoming. Because of this change Dr. Reed has resigned as editor-in-chief and manager, but will remain with the paper as one of the associate editors. Dr. J. E. Brown will succeed him as editor and manager, and will be assisted by Drs. J. D. Dunham and T. L. Chadbourne.

"The International Medical Magazine."—Beginning with the new year Dr. Henry W. Cattell retires from the editorial management of this journal, being succeeded by Dr. Walter L. Pyle.

Examinations for the Marine Hospital Service.—A board of officers will be convened at Washington, D. C., January 25, 1898, for the purpose of examining for admission to the grade of assistant surgeon in the United States Marine Hospital service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character. In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations on the cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are as a rule first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examinations for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, or $50 a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per cent. in addition to the regular salary for every five years' service, up to forty per cent. after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. Those desiring further information or an invitation to appear before the board of examiners may address Dr. Walter Wyman, supervising surgeon-general of the U. S. Marine Hospital service, Washington, D. C.

The Late Dr. Joseph O'Dwyer.—At a regular meeting of the medical board of the Willard Parker and Riverside hospitals, held January 11, 1898, the following resolutions were unanimously adopted:

"*Whereas,* We have learned with profound regret of the death of Dr. Joseph O'Dwyer; and

"*Whereas,* This board has been frequently indebted to the wise counsel and unfailing courtesy of Dr. O'Dwyer in many difficult cases of intubation; and

"*Whereas,* An institution specially devoted to the treatment of diphtheria is under lasting obligation to the genius of Dr. O'Dwyer, and can best appreciate the life-saving character of his invention; therefore be it

"*Resolved,* That we feel we have lost by the death of Dr. O'Dwyer a friend who combined, in rare degree, modesty with great attainments.

"*Resolved,* That the medical profession has lost one of its most distinguished members, whose work on intubation of the larynx reflects lasting credit on American medicine, and has perhaps resulted in saving more lives than any one surgical invention of the century.

"*Resolved,* That copies of these resolutions be forwarded to the medical press of New York, and to the family of the deceased.

"Henry D. Chapin, M.D.,
"Henry W. Berg, M.D.,
"*Committee.*"

Obituary Notes.—Dr. Samuel H. McIlroy, of this city, died at his home in Alexander Avenue, on January 5th, at the age of fifty-eight years. He served as assistant surgeon in the Union army during the civil war.—Dr. Caroline M. Dodson died in Philadelphia, on January 9th, at the age of fifty-two years. She was a graduate of the Woman's Medical College of Pennsylvania in 1874. She was an active member of many women's associations for the promotion of temperance, public health, the suffrage, etc., and was also the founder of the Baptist Sisterhood.

The Thirteenth International Medical Congress.—Active steps are already being taken by a committee in Paris, of which Dr. Brouardel, the dean of the Medical Faculty, is chairman, to arrange the preliminary details of the International Medical Congress which is to take place in that city in 1900.

Relief for the Suffering in Cuba.—It is announced that after consultation with the authorities in the State department, the officials of the American Red Cross Society have arranged to open headquarters in New York for the reception and forwarding to Havana of contributions for the benefit of the suffering Cubans. Miss Clara Barton will be in charge of the New York office. The Ward's Line Company will furnish free transportation in their ships for all supplies sent to Cuba in response to Secretary Sherman's appeal. That there is urgent need of relief for the victims of Weyler's policy is clearly shown by an article recently published in the *Diario de la Marina*, of Havana. According to this article the population of the province of Matanzas on December 31, 1896, was 253,616 persons. The order of concentration compelled 99,312 persons to abandon their homes, and these were herded in the towns without any resources. Up to November 30, 1897, 20,044 of these people had died of starvation and 17,456 had disappeared. It is estimated that there are at the present time over 62,000 persons, 17,000 men, 20,000 women, and 25,000 children, in that province alone who are slowly dying from inanition and famine diseases. Taking these figures as a basis, it is believed that no less than 500,000 deaths from starvation alone are directly traceable to General Weyler's edict of concentration. The consul-general of the United States at Havana mentions the following articles as appropriate to be contributed, all of them, as he reports, being greatly needed. Summer clothing for women and children; quinine; hard bread, flour, cornmeal, cereal preparations, bacon, rice, lard, potatoes, beans, peas, salt fish; any canned goods, particularly nourishing soups; meat extracts, blankets, and especially large quantities of condensed milk. Contributions of money are also urgently needed to enable the purchase of immediate supplies of medicines and articles of prime necessity and to meet the expenses of local transportation in Cuba.

The English Typhoid Epidemics.—The total number of cases of typhoid fever during the recent epidemic at Lynn is reported to have been four hundred and forty-nine, with a death rate of just under ten per cent. The Maidstone epidemic was much larger, there having been eighteen hundred and eighty-nine cases.

The Care of Lepers.—A dispatch from New Orleans states that the Louisiana leper board, which has charge of the leper home at Indian Camp, Iberville Parish, has received a letter from New York, asking the Louisiana home to take charge of the lepers recently sent adrift in New York in a destitute condition by the action of the board of health. The Louisiana board replied that it could not care for pauper lepers from other States, but that it would accept the New York lepers if a guarantee were given that their board would be paid for regularly.

The Louisiana State Medical Society.—The next meeting of this society will be held in New Orleans on May 10, 11, and 12, 1898. No meeting was held in 1897, because of the uncertainties caused by the Mississippi floods.

Dr. Herman C. Evarts, of this city, has been appointed medical superintendent of the Kingsports division of the Long Island State Hospital. The appointment was made from the civil service eligible lists. Dr. Evarts was formerly an assistant physician at the Manhattan State Hospital.

The Central Texas Medical Association.—The semiannual meeting of this association was held at Hillsboro, Tex., on Tuesday and Wednesday, January 11th and 12th. The president of the society was Dr. W. C. Ballock, and the secretary Dr. M. L. Graves. This was the first time a meeting of the association has been held elsewhere than at Waco.

A Physician Shot.—A prominent physician of Memphis, Tenn., was fatally shot by a woman with whom he was driving, on January 7th. After mortally wounding her companion, the woman killed herself with the same weapon.

Sanatoria and the Law.—The managers of a sanatorium for consumptives have brought a motion on before Justice Beekman of the Supreme Court, to compel the department of buildings to approve its plans for remodelling two houses for hospital purposes. The department would not approve the plans because the building was not to be fireproof, holding that it was without discretion, as under the law of 1892 all hospitals over thirty-five feet high must be fireproof. To the casual observer there would appear to be no good reason why the laws should be changed to accommodate private hospitals or individuals.

Yellow Fever Serum.—Dr. Sanarelli has sent some yellow-fever serum to Surgeon-General Wyman, of the Marine Hospital service, and to Dr. Doty, health officer of the port of New York. It is rather too late to be of much service now, for even in Havana there is scarcely any yellow fever at the present time, only two deaths from this disease having been reported for the week ending December 25th. Concerning this serum, Dr. Sanarelli writes that he cannot offer it as a sovereign remedy for yellow fever, but believes that the serum would prove efficacious whenever administered during the early stages of the disease.

Obituary.

JOSEPH O'DYWER, M.D.,

NEW YORK.

Dr. Joseph O'Dwyer died at his home in this city on the evening of January 7th, after a brief though painful illness. He was born in Ohio in October, 1841, but passed his early life in Canada. His academic course was completed at McGill University, Montreal, and his medical course in this city, where he was graduated from the College of Physicians and Surgeons in the class of '66. After graduation he served a term as interne in the City, then Charity, Hospital, and afterward as examining physician at Bellevue Hospital. He was a member of many local and national medical societies, an ex-president of the American Pediatric Society, and was attending physician to the New York Foundling Asylum and to St. Vincent's Hospital, and consulting physician to the Seton Hospital. His family consisted of four sons, his wife having died over nine years ago.

For twenty years before intubation of the larynx was heard of, Dr. O'Dwyer was engaged in the practice of his profession, winning for himself the esteem of his patients, the warm affection of his friends, and the respect of his fellow-physicians. He was, however, of a most retiring disposition, anything in the way of "push," even of the most legitimate and praiseworthy kind, being utterly repugnant to his nature, and he would have lived and died among the unknown heroes of medicine had it not been for the invention which made him famous in spite of himself. He worked quietly but perseveringly in the development of his ideas, with the knowledge but not always the encouragement of his colleagues on the medical staff of the Foundling Asylum, until he had assured himself that the procedure was of life-saving value. Then he published it to the world, not from any desire for fame or for pecuniary reward, but against his own inclination, and simply because he believed that it was his duty to God and to his fellow-man to make known to others a means whereby so much suffering could be alleviated and so many lives saved. Afterward he learned to his great surprise that the principle of intubation had been advocated many years before by Bouchut in Paris. Dr. O'Dwyer's invention was, however, absolutely original with himself, for he had conceived the idea and had perfected his tubes, which differed from those of Bouchut as much as one cylinder can possibly differ from another, months before he had ever heard of the latter's method and its speedy condemnation by the leaders of the French profession of that day. To those whose privilege it was to know Dr. O'Dwyer intimately the mere suggestion that he was capable of appropriating another's idea and calling it his own was mirth provoking.

A few days before Dr. O'Dwyer's death a notice appeared in the daily papers to the effect that he was suffering from tuberculous meningitis, having diagnosed his own condition. The following brief sketch of his illness and of the post-mortem findings will show how incorrect was this report, which was, moreover, wholly unauthorized by the physicians in attendance. About five weeks before his death Dr. O'Dwyer suffered from a carbuncle on his chin, which healed kindly enough, but was followed soon after by a furuncle on the upper lip. Four days after the carbuncle appeared he was suddenly seized with intense vertigo, nausea, and vomiting, with severe tinnitus and absolute deafness in the right ear. There was no rise in temperature but the pulse was irregular and intermittent, as it had been, however, at times for a considerable period prior to this attack. The ear symptoms pointed to a sudden lesion of the labyrinth or auditory nerve. After these symptoms had continued for about two weeks there began to be pain in the head deeply seated on the right side, but later more generally diffused and described as of a band encircling the forehead. About a week before death, the pains increased in severity and symptoms of meningitis appeared. The temperature now rose rapidly, reaching 103° F., and exceeding 105° F. toward the end. The pulse was quite constant at from 60 to 68 until the last days. Five days before death a right-side paralysis of the face appeared, and four days later paralysis of the left arm and leg. Along with the rigidity in the neck and spinal muscles and other signs of meningitis there supervened delirium with increasing stupor, which passed into coma shortly before the end. Death came peacefully at ten o'clock on the evening of Friday, January 7th. The autopsy showed that death was due to thrombosis of the basilar artery with softening of the right lobe of the cerebellum and in the right half of the pons, together with localized meningitis.

And so died a man whose unassuming modesty, perfect charity, honesty of purpose, and nobility of character endeared him to all who were honored by his friendship. His place in medicine will be difficult to fill; the loss to those who loved him is irreparable.

ERNEST ABRAHAM HART, D.C.L., M.R.C.S.,

LONDON.

Mr. Ernest Hart, editor for thirty years past of the *British Medical Journal*, died on January 7th, after a long and patient struggle against a fatal malady. He was born in June, 1836, and received his early education at the City of London School. He studied medicine at the St. George's Hospital Medical School and was admitted to membership in the Royal College of Surgeons in 1856. He soon began literary work and was for a time assistant editor of *The Lancet*, later having editorial supervision of the *Sanitary Record* and of the *London Medical Recorder*. He was appointed editor of the *British Medical Journal* in 1866, and with brief interruption continued in charge of that periodical up to the time of his death. Mr. Hart was an earnest advocate of many sanitary and social reforms, and lived to see most of his plans put into force in spite of the bitter opposition. He was known as a strong believer in the theory that the poisons of cholera and typhoid fever are conveyed in the drinking-water, and he preached and upheld this doctrine before even it was known of what nature these poisons were. At the meeting of the American Medical Association in Milwaukee in 1892, Mr. Hart read a paper on "water-borne diseases," in which he adduced many striking proofs of the truth of this theory, and told in a most interesting manner of his early triumphs in forcing conviction upon unbelievers during the course of various epidemics of cholera in Italy and elsewhere. In the latest volume of the "Twentieth Century Practice" there is an article from his pen on the same subject. Among the social measures which he was instrumental in putting through was one leading to improvement in the condition of paupers in English workhouses. The passage of the infant-life protection act by Parliament was the direct result of his report on baby farming, and he was also mainly instrumental in the establishment of coffee taverns in the East End, from which much was hoped for in the diminution of intemperance. A few years ago he was led to investigate the condition of the Irish peasantry, the practical outcome of which was some legislation looking to the establishment of a peasant proprietary, together with the reclamation of certain waste land in Ireland, and also the establishment, with his wife's assistance, of the Donegal industrial fund for developing home industries, lace making, and the like, among the daughters of the Irish cottagers. He established a society for the abatement of the smoke nuisance in London, and as chairman of the parliamentary-bills committee of the British Medical Association he was active in promoting many measures of a more strictly medical nature.

For many years Mr. Hart had been in feeble health, but he remained in harness to the end, having only recently undertaken to edit a series of biographies of medical men of the past, he himself writing one of the early volumes. A few months ago he suffered an amputation of the leg on account of necrosis of the bones of the foot complicating diabetes, but he rallied well from the operation and his friends had every hope that his useful life might be spared for yet many years. But it was only the temporary mastery of the body by a strong will. The disease overcame him at last, and so went out from among us one who had done much for the good of his profession and of the community in which he lived.

Reviews and Notices.

A Treatise on Gynæcology, Medical and Surgical. By S. Pozzi, M.D., Professeur Agrégé à la Faculté de Médecine de Paris, Chirurgien de l'Hôpital Broca, Membre de l'Académie de Médecine. Second American Edition, Translated from the Third French Edition, under the supervision of Brooks H. Wells, M.D., Editor of the *American Journal of Obstetrics*, Adjunct Professor of Gynæcology at the New York Polyclinic, Fellow of the New York Obstetrical Society and the New York Academy of Medicine. With Six Hundred Illustrations. Pp. xiv. + 936. New York: William Wood and Company. 1897.

As the editor states in the preface, the success of Professor Pozzi's work has been such as to justify a new translation of the third French edition, which is itself essentially a new book. The present American edition offers an important advantage over the former one, as it is included in a single volume, which presents even more features of excellence than its predecessor. The careful work of the editor appears in the numerous bracketed comments and references to American operations.

The preliminary chapters on gynæcological technique and methods of examination are still as attractive as ever. Under the head of "Metritis" are considered a number of pathological conditions which are usually treated separately in text-books. We have always regarded this portion of the work as the least satisfactory of all, though the chapter on treatment is excellent. Chapters viii. to xvi., inclusive, on uterine fibromata and carcinoma, and chapter xxiii., on uterine displacements and disorders of menstruation, are thoroughly up to date.

Diseases of the adnexa are exhaustively treated. The chapter on genital fistulæ and laceration of the perineum are full and richly illustrated. The index, like that in the former translation, is worthy of especial praise.

While there may be features of this admirable work not entirely in accord with American ideas, especially as regards pathology, and the arrangement is sometimes confusing, it still remains a model of its kind, and should be in the library of every special worker. As a book for the advanced student, and as a work of reference, especially in surgical gynæcology, it will be long before its superior appears. Those who have hesitated about purchasing the two-volume edition can hardly resist the new translation in its present attractive form.

A Handbook of Midwifery. By W. R. Dakin, M.D., B.Sc. Lond., F.R.C.P., Obstetric Physician and Lecturer on Midwifery and Diseases of Women to St. George's, etc. With 400 Illustrations, nearly all of which are original. Pp. xx. + 629. London: Longmans, Green & Co. 1897.

This is a fresh and decidedly interesting work, not the least attractive feature of which is the absence of the hackneyed illustrations which have been copied from the text-books of preceding generations. Moreover, the arrangement of the subject matter is somewhat novel and presents certain advantages for the student. There are two main divisions, the first (including thirty-four chapters) dealing with physiology, the second (forty-two chapters) with pathology. Under the former subject are included the physiology of pregnancy and labor, the mechanism of labor, the physiology of the puerperal period, and the physiology and care of the new-born; under the head of pathology are treated the pathology of pregnancy, obstetric operations, the pathology of labor and of the puerperal period, and, lastly, the pathology of the new-born. It will be evident that this sequence is not only a natural one, but is an important aid to the author in preserving the unity of his work. In a book of such general excellence it is not easy to select special points of merit. Clearness and conciseness, with a severe simplicity, are its distinguishing features. The author has been uniformly successful in his attempts to "avoid the waste of space and the confusion of the reader's mind which would be incurred by inserting all the most recent pathological speculations and the newest details of treatment." He has apparently no pet hobbies to ride, and, unlike most writers, does not devote a disproportionate amount of space to a detailed description of some pet operation. We note with especial approval the careful attention bestowed upon the mechanism of labor (chapters xvi. xxi.), with the numerous original illustrations. The sections on the management of normal labor and of the puerperal period are thoroughly practical and up to date. The chapter on abortion is a model of brevity and common sense. Ectopic gestation receives the attention which its importance demands. The chapter on hemorrhages concludes with an epitome (page 351), which will be found especially helpful to the student.

In the section on obstetric operations it will be noted by the reader with some surprise that the author prefers the old lateral position; also that he does not favor the use of the axis-traction instrument. No mention is made of the modern method of subcutaneous saline solution in hemorrhage. The paragraph on the management of occipito-posterior positions is rather vague and unsatisfactory. The description of the repair of perineal lacerations is hardly up to modern requirements, and we do not agree at all with the statement that hemorrhage from laceration of the cervix is "best treated by plugging the cervix for a few hours with iodoform gauze, for attempts at suture—which would, if feasible, be the correct treatment—are practically useless." Surely this is not the experience of American obstetricians. Under the head of eclampsia no reference is made to rapid dilatation, manual or after multiple incision of the cervix. The treatment of puerperal septicæmia is judicious and conservative.

The index is unusually full; there are also an index of authors and a list of illustrations. Especial mention should be made of the latter, which constitute an important feature of the book.

We take pleasure in commending this work, even though some of the author's dicta sound strangely to our ears. It is full of valuable practical suggestions, and is clearly the outcome of mature experience in the lecture room and at the bedside.

Experimentelle und kritische Studien über Säuglingsfäces bei natürlicher und künstlicher Ernährung. Von Dr. Magnus Blauberg. Berlin: Verlag von Hirschwald. 1897.

Blauberg in this monograph presents his valuable investigations with regard to the physiology of the infant's fæces. Their chemical composition under different modes of feeding has been thoroughly studied and the results have been made known.

A Manual of Obstetric Practice for Students and Practitioners. By Prof. A. Dührssen, M.D., late First Assistant in the Obstetric Clinic of the Charité Hospital in Berlin. Translated and edited from the sixth amended and enlarged edition by John W. Taylor, F.R.C.S., Surgeon to the Woman's Hospital, Birmingham, and Frederick Edge, M.D., F.R.C.S., Surgeon to the Woman's Hospital, Wolverhampton. With Illustrations. Pp. xviii. + 304. London: H. K. Lewis. 1897.

The excellence of this little manual is attested by the rapid appearance of successive additions in the original German. The author's name is so well known among obstetricians that the reader is assured that his work will be fully abreast of the times. Although the subject matter is necessarily much condensed, clearness is not sacrificed to brevity.

The sections in aseptic preparations (pages 53 to 60) are especially valuable, and should be mastered by every practitioner, especially the dictum that "before the examination the disinfected hand should touch nothing but the genitalia without being redisinfected." The advice to examine thoroughly under anæsthesia in every doubtful case before applying forceps is timely.

It cannot be said that the section on the management of occipito-posterior positions is particularly helpful to the student, but this is a subject on which most text-books are singularly vague. Abortion is thoroughly treated, as its importance demands. Under the head of uterine inertia (page 137), we note the somewhat contradictory statements: "In case delivery is undertaken for inertia, fifteen to thirty minims of ergot, or an injection of ergotin is given shortly before," etc.; and in the next sentence, "The practitioner should entirely give up the preliminary use of ergot in the first two stages of labor." The chapter on eclampsia is interesting, as it contains a description of the author's method of rapid delivery by incision of the cervix; that on post-partum hemorrhage by reason of the detailed account of his treatment by intra-uterine tamponade (pages 197, 198).

An appendix (including seventy-five pages) is devoted to operative technique, and contains a remarkable amount of information within a small space. The reader will find the paragraphs on dilatation of the cervix, version, and forceps of peculiar interest. In a concluding section the author describes the bold and ingenious procedure which he calls "vaginal Cæsarian section."

INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, U.S.A. Authors and Subjects. Second Series. Volume II. B—Bywater. 4to, pp. 954.

THIS volume, uniform in size with the preceding one, includes 15,732 author titles, 5,744 subject titles, and 21,725 titles of articles in periodicals. It has been compiled under the direction of D. L. Huntington, Deputy Surgeon-General and Lieutenant-Colonel, United States army.

ESSENTIALS OF OBSTETRICS. By CHARLES JEWETT, A.M., M.D., Sc.D., Professor of Obstetrics and Pædiatrics in the Long Island College Hospital and Obstetrician to the Hospital, assisted by HAROLD F. JEWETT, M.D. Illustrated by 80 wood cuts and 3 colored plates. Pp. 358. Philadelphia and New York: Lea Brothers & Co. 1897.

It would seem somewhat ungracious to begin a review by asking the *raison d'être* of a book, but the question is a natural one on the appearance of a new manual of obstetrics, a branch of medicine which has already a voluminous "current literature." But in this instance the name of the author leads one to infer that this is not an ordinary quiz compend. It is in fact a compilation from recent text-books, but reinforced and enriched by the experience of an experienced teacher and accoucheur. We have no hesitation in stating that this manual accomplishes all that is claimed for it in the modest preface.

In chapter iii. the reader will note as especially valuable the paragraphs on obstetric palpation, the aseptic preparation for and conduct of labor, and the immediate repair of lacerations. In chapter iv. careful attention is paid to the subject of infant feeding, which is usually slighted in the larger text-books on obstetrics, to ophthalmia neonatorum, and to early intestinal derangements. In passing we note with approval the section on abortion and pernicious vomiting. The treatment of the occipito-posterior position receives considerable attention (pages 240–242), but one is surprised to find that no mention is made of version when the head is above the brim as a substitute for the equally difficult and less certain correction of the position by combined internal and external manipulation. The subjects of hemorrhage, eclampsia, and puerperal septicæmia are well handled. The concluding chapter on obstetric operations contains a brief but lucid description of symphyseotomy.

An excellent index concludes the manual, which is certainly one of the best and most scholarly that have yet appeared. The practitioner and the student will alike find it useful, not only as a means of refreshing his knowledge of facts once familiar, but as an epitome of the most recent advances in the obstetric art.

SLEEP: ITS PHYSIOLOGY, PATHOLOGY, HYGIENE, AND PSYCHOLOGY. By MARIE DE MANACÉÏNE (St. Petersburg). 12mo, pp. 335. London: Walter Scott (Limited). New York: Charles Scribner's Sons.

UNDER the different headings named in the title are collected some very useful and interesting facts connected with the phenomena of sleep. Physiologically speaking, it is rightly claimed as nature's restorer for wasted energies of body and brain, the whole being comprised in the temporary arrest of consciousness and that quiescence of organic processes which reduce tissue waste to the minimum and give freest possible scope to recovery of tone. The author accepts the apparently well-founded theory that physiological sleep is due to cerebral anæmia and gives some telling proofs in its support.

"The Hygiene of Sleep" presents a very graphic picture of several conditions of environment which influence it for good or evil, as well as the purely subjective ones, natural or acquired. Dual personality is discussed in a very interesting and instructive way, with leading illustrative cases. The chapter on dreams presents some very curious facts, which cannot fail to edify all such as are curious regarding the scientific explanation of psychic phenomena. The part of especial interest to the practitioner will be that which treats of insomnia and its allied conditions. He will be surprised and edified to learn how much can be accomplished without drugs when the fundamental relations of cause and effect are properly understood.

A MANUAL OF MEDICAL JURISPRUDENCE. By ALFRED SWAINE TAYLOR, M.D., F.R.S. Revised and Edited by THOMAS STEVENSON, M.D., London. Twelfth American Edition, with Citations and Additions from the Twelfth English Edition. By CLARK BELL, Esq., LL.D., President of the American International Medico-Legal Congress of 1889, etc. 8vo, pp. 832. Philadelphia and New York: Lea Brothers & Co.

THE well-established reputation of this manual and its long acceptance as the leading authority on the subject need not be told. This is the twelfth American with citations and additions from the twelfth English edition, and is admirably edited by Charles Bell, Esq., who is well known in medico-legal circles as a tireless student of the particular branches of forensic medicine of which this work treats. He has enriched the present edition by citations of nearly seven hundred new cases and authorities, which add an incalculable value to the intrinsic worth of the book as a whole. It is unnecessary to say that this jurisprudence is, as it always has been, a model of its kind.

A TEXT-BOOK OF GENERAL BOTANY. By CARLTON C. CURTIS, A.M., Ph.D., Tutor in Botany in Columbia University. 8vo, pp. viii. + 359, Figs. 87. New York: Longmans, Green & Co. 1897.

THIS work is divided into three sections, viz.: "Anatomy," "Physiology," and "Systematic Botany and Morphology." Under the first are described the plant cell—its contents, formation, and growth—and then the development of the perfect plant. The section on physiology is succinctly though clearly treated, while the larger part of the book is devoted to the classification and divisions of the vegetable kingdom. It does not profess to be adapted for the use of those who desire and have the time for but a general idea of the elements of the science, but for others, who wish to lay a broad and sound foundation for the study of botany, it is certainly a most clear and thoroughly scientific introduction. Its suggestions for laboratory work are suggestive, interesting, and practical. It is well illustrated with mostly original drawings, and superior in its general "get up" to most text-books upon the subject.

TEXT-BOOK OF MEDICAL AND SURGICAL GYNÆCOLOGY. For the Use of Students and Practitioners. By R. W. GARRETT, M.A., M.D., Professor of Obstetrics and Gynæcology in the Medical Faculty, Queen's University, Kingston; Gynæcologist to the Kingston General Hospital. Containing over One Hundred Illustrations. Pp. 419. Toronto: J. A. Carveth & Co.

THIS book is essentially a collection of clinical lectures, in the preparation of which the author has borrowed freely from modern text-books and systems. Considerable care and judgment have been exercised in the selection and arrangement of the subject matter, and the illustrations, though not original, are clearly reproduced. The subdivisions are rather unique. Under Part I. are included ten chapters on development, anatomy, operative technique, anæsthetics, and "gynæcological therapeutics." Part II. contains only two chapters, one on the disorders of menstruation, and another on the widely diverse subjects, sterility, nymphomania (!), and leucorrhœa. Under Part III. are grouped the diseases of the genito-urinary tract in the usual order, except that affections of the urethra and bladder follow those of the vagina. Part IV. (two chapters) deals with mammary diseases and neoplasms.

The descriptions of operations are clear and intelligent, and the sections on pathology contain just enough information for the student, without being too dry and dogmatic.

The index is carefully prepared. The book is evidently the work of a practical teacher as well as a thorough student of the literature of gynæcology, and is far superior to the ordinary manuals and quiz compends with which this branch of medicine is burdened. It should not be dismissed after a superficial reading, but deserves respectful consideration and a place as a real aid to the student in the acquisition of a working knowledge of this important subject.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 6, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

Annual Reports.—The membership of the academy is at present composed of eight hundred and fifteen resident and ninety-nine non-resident members. The committee has acted during the past year upon sixty-four applications for membership. It is pleasant to record that the only remaining indebtedness is a note for $7,000, and it is hoped that this will soon be effaced. The total number of books and periodicals in the library is 38,320, and, with the steadily increasing number of readers, the want of an adequate endowment for the library is felt more keenly than ever before.

Clinical Observations on Malaria, and Its Treatment.—DR. BEVERLEY ROBINSON read a paper with this title (see page 73).

What is Malaria?—DR. ANDREW H. SMITH said that before entering upon a discussion of malaria we should agree upon what was meant by the term "malaria." If we could not find the specific organism we should at any rate insist upon some degree of periodicity as a test for the presence of the disease. To attach this term to a protracted deterioration of the health, with or without more or less febrile disturbance, was a common mistake. In this city some of these cases might be attributed to the persistent influence of the inhalation of sewer gas. A case was cited in which a child of three years had suddenly become ill without any definite general or local symptoms. On careful inquiry it was ascertained that the child, while taking its daily bath in the tub, was allowed to stoop over the opening in the exit pipe and watch the water as it ran out. This practice was stopped, the further inhalation of sewer gas was prevented, and the little one's accustomed health was soon restored. The physician should be constantly on guard against making a diagnosis of malaria simply because of the presence of chills. Last summer he had seen a case that had been under the care of a number of medical gentlemen. A specimen of blood was examined, and although no plasmodium could be found there were some free pigment granules. This continued for some time, and then an ischio-rectal abscess suddenly made its appearance. Previous to this the patient had been repeatedly interrogated as to the existence of pain or tenderness in any part of the body, but had always replied in the negative. On evacuation of the pus from the abscess, the so-called malaria promptly subsided.

Prevalent at the Seashore.—He had seen again and again at the seashore, in a locality where malaria was not at all indigenous, the development of this disease, repeated on several successive seasons. It was a popular idea that, a person having once absorbed a heavy dose of malaria, relapses would occur over a period of many years. The malaria of certain localities seemed to be peculiarly persistent—he believed the southern and eastern shores of Staten Island had that reputation.

Susceptibility to Quinine.—The susceptibility to quinine exhibited by some persons could be nearly always overcome by giving the quinine with hydrobromic acid or the bromides—for example, twice as much bromide of sodium as quinine. He favored the use of the muriate of quinine instead of the sulphate. One reason for this preference was the very material difference in the alkaloidal strength, the muriate having eighty-one per cent. as against seventy-four per cent. for the sulphate. Again, one part of the muriate was soluble in twenty-two parts of water, while the sulphate required five hundred and eighty-one parts of water for its solution.

Large Doses of Quinine not Necessary.—It was beginning to be recognized that the enormous doses given in the past were not of any particular value. If we regarded the quinine as acting directly upon the malarial organism, inasmuch as that organism was contained in the blood and not in any part of the body, it was possible to influence the blood by comparatively small quantities of quinine. It had been estimated that five grains of quinine dissolved in the blood would represent a solution having a strength of 1 to 10,000, whereas 1 to 20,000 had been shown to be sufficient, as it were, to paralyze the plasmodium.

Double Infection with Malaria and Typhoid.—With reference to the coincident occurrence of malaria with typhoid fever, the speaker said that he had seen at least two cases within a short time, about which he felt certain as to the diagnosis. In these, careful and competent examiners had proved the presence of the plasmodium of malaria, and Widal's test had demonstrated the presence of typhoid fever. In each case the malarial infection had been at the beginning and the typhoid at the close.

Arsenic Slow but Sure.—While we could cure most cases of undoubted malaria with quinine, there might be some well-defined cases which would baffle us. Just in proportion as the periodicity is marked were we likely to be successful with quinine. While arsenic was much slower than quinine in producing its result, the effect was more permanent.

Quinine and the Bromides.—DR. LOUIS FAUGÈRES BISHOP said that when the Home for Consumptives was moved from Fordham to St. Luke's Hospital many of the patients were having chills, supposed to be due to a combination of tuberculosis and sepsis. A careful study of the temperature had shown a certain periodicity resembling malaria, and when quinine was administered the malarial part of the temperature curve was eliminated. A short time ago he had seen a patient in whom the chills had not been controlled by small doses of quinine, but when this drug had been combined with bromides the beneficial effect was much more marked, probably through the influence of the remedy on the nervous system.

Capsicum and Taraxacum Aid Quinine.—DR. ALBERT W. WARDEN referred to the peculiar depression and malnutrition exhibited by those suffering from malaria. It was for the latter condition, he thought, that arsenic was so beneficial, but if the secretions were much altered arsenic would not be tolerated. In his practice he had found it very useful to combine quinine with capsicum and taraxacum. It was useless to give much quinine until free catharsis had been produced, and it was important to increase the dose of quinine about the eighth or ninth day. The treatment for malaria seemed to be aided by allowing the patient to drink freely of lemon juice. He had not observed any benefit from the use of the bromides with quinine. For the more chronic cases the syrup of the iodide of iron was indicated, not only to hasten convalescence but to prevent recurrence.

DR. ROBINSON, in closing, deprecated the prevailing tendency at the present time to lay so much stress on laboratory research, as opposed to clinical observation.

Clinical Observations upon the Heart and Circulation in Diphtheria.—DR. HENRY DWIGHT CHAPIN presented a paper on this subject, but, owing to lack of time, read only portions of it (see page 77).

What is Heart Failure? DR. A. JACOBI asked what was meant by that term which was in everybody's mouth—"heart failure." When the muscular tissue was anæmic and emaciated there was muscular

failure, and whatever happened in the voluntary muscles, as of the extremities, would also happen in the heart muscle; and so without much anatomical change there might be even a dangerous weakness of the heart muscle. The result of the consequent enfeeblement of the circulation would be the formation, first, of small and then of larger thrombi in the heart. As these could not be gotten rid of, they constituted a cause of death. All this might occur in a heart which had undergone but little change, and such a weakened heart might be found in various infectious and inflammatory diseases, or even in cases of inanition. Another form of heart failure was that observed in the course of typhoid, scarlet fever, and even whooping-cough. Many physicians were too slow in recognizing the important part played by the myocardium in the circulation. In the infectious diseases the changes which might take place in the heart might be only interstitial, and the outcome would be the same as in other organs in which such change took place—first hyperplasia and later cicatrization. This form was not frequent in infectious diseases. In a number of bad cases abscesses would be found in the myocardium, and they might even rupture into the pericardium. Exceptionally they ruptured into the general circulation and caused death. Most of the cases of parenchymatous inflammation coming under observation were those in which granular and hyaline degeneration took place, sometimes to such an extent that the muscular tissue became quite friable. The technical term "fragmentation" had been applied to such cases. They presented all the symptoms of absolute failure.

Danger Signals.—The reader of the paper had called attention to the slowness sometimes observed in the heart action. This was the result of the incompetency of the heart. Sometimes the heart action was very rapid because it was only by such rapid action that the circulation could be sustained. Danger was imminent when the second sound of the heart became feeble or inaudible. If there was an equal interval between the two heart sounds, it should be looked upon as a sign of a weak heart, and of impending danger. Except in cases of "fragmentation," death almost invariably occurred.

Many Lives Sacrificed to Expectant Treatment.—What cannot be cured, Dr. Jacobi said, need not be endured—it ought to be prevented. We were on the wrong track when we spoke of the necessity of a so-called "expectant" treatment. This waiting, Micawber-like, for "something to turn up" was fraught with great danger, and had caused the sacrifice of many lives. It was far better to administer heart stimulants in the early stages.

Our Ignorance Regarding this Heart Failure.—Dr. Joseph E. Winters expressed the belief that we were in absolute ignorance regarding this very important subject of heart failure in diphtheria. He would like very much to know why the toxins of diphtheria at one time affected the inhibitory fibres of the pneumogastric, and at another affected the vaso-excitor fibres; why in one instance there would be an exceedingly rapid pulse, and in another an extremely slow pulse. It was a condition about which we knew absolutely nothing, and which we were almost powerless to treat.

Slow Pulse and Antitoxin.—The exceedingly slow pulse of diphtheria had received little or no consideration in the text-books, and was a phenomenon of diphtheria which he had not personally observed until within the last two years. There was another feature of it, *i.e.*, that the more freely the antitoxin was used the more frequently was this very slow pulse observed. Whether or not there was any connection between these conditions he did not know. In treatises on diphtheria in which any mention was made of this very slow pulse it was said to be of very rare occurrence, yet recently he had seen a great deal of it at the hospital, and it was a far more dangerous condition than extreme rapidity of pulse. He recalled only two cases of recovery when the pulse had been very slow, yet there were numerous instances in which recovery had followed upon a very rapid pulse. In the case cited in the paper, in which the pulse sank to 28 per minute, six thousand units of antitoxin had been administered. A year ago last December these very large doses of antitoxin had been begun in the hospital, and at this time there had been many of these cases of slow pulse. At present these large doses were not given so much, and the slow pulse was less frequently noted. For example, a young lady of seventeen, from one of the private schools, received three thousand units of antitoxin, and after three or four days, the local condition not being satisfactory, she was given another dose of three thousand units. In a short time the pulse fell to 26 per minute, in spite of all treatment, and the case terminated fatally on the following day. When to this cardiac depression vomiting was added, death was the invariable sequel.

Heart Failure Not Always Preventable.—As to the management of this condition Dr. Winters said he did not think we could do any more in the way of preventing this change in the heart beats than we could in the treatment of it when actually present. In some cases it would occur in spite of every care and precaution. In other cases in which there seemed to be reason to expect it, it did not occur. Probably the explanation was to be found in the fact that some of the patients were extremely susceptible to the toxin of the disease, while others were comparatively immune. In confirmation of this he called attention to the well-known fact that in these infectious diseases there was extreme fatality in some families, while in others it was extremely mild. This was true of scarlet fever as well as of diphtheria, so much so that when the first patient in a household died of scarlet fever there was good reason to expect that others in the family would also die if stricken with the disease. This was the reason why it was reported that sometimes in one family as many as five or six died, while in another family, in which there was just as much local evidence of the disease and just the same treatment was employed, most of the sick ones recovered.

Does Not Approve of Strychnine.—He had seen all sorts of treatment tried for both the slow and the rapid pulse of diphtheria. Strychnine was used very largely now in cases exhibiting a tendency to cardiac depression, yet he did not feel at all sure that it did any good. A few days ago he had had a conversation on this subject with Dr. W. M. Welch, of Philadelphia, a physician who had constantly studied diphtheria for nearly thirty years. This gentleman had expressed the opinion that strychnine did no harm, but he was equally sure that it did no good. Dr. Winters said that there was nothing in the physiological action of strychnine to warrant us in expecting any benefit from its use in these cases. In his opinion alcohol came first on the list, and when needed it should be given in very large doses. Alcohol was much less likely to cause vomiting when given alone, and in the later stages of the disease vomiting was as dangerous as the rapid pulse. If he added anything to the alcohol it would be camphor or caffeine rather than strychnine.

Dr. H. W. Berg said that fully eighty per cent. of cases of diphtheria showed nothing characteristic in the pulse. There were cases, however, in which a specific effect was seen—the cases of slow pulse occurring frequently as a complication in very severe attacks. Long before he had been connected with a diphtheria hos-

pital he had seen this slow pulse occasionally in bad cases of diphtheria. He recalled distinctly seeing such a case in consultation with Dr. Jacobi fourteen years ago—in other words long before the introduction of the antitoxin treatment. Although large doses of antitoxin had been used freely in the hospital during the past year, he could not say that he had met with many cases in which the pulse had been slow. He deprecated the apparent tendency shown to find fault and to pick flaws in such special methods as the antitoxin treatment.

Midwifery Legislation.—At the last meeting of the academy Dr. Brill moved that a committee of three be appointed to confer with similar committees from other societies regarding this matter. After some discussion at the present meeting the motion was carried without much opposition.

THE PRACTITIONERS' SOCIETY.

One Hundred and Thirty-fifth Regular Meeting, Held Friday, December 3, 1897.

DR. W. GILMAN THOMPSON, PRESIDENT, IN THE CHAIR.

Plastic Operation for the Relief of Deformity Due to Double Harelip.—DR. ROBERT ABBE presented a young man, twenty-four years old, upon whom he had recently operated for the relief of a disagreeable defect of the lower part of the face. (This case will appear in full in a future issue.)

Neuritis and Atrophy Following Acute Arsenical Poisoning.—DR. W. GILMAN THOMPSON presented a man, thirty-eight years old, who last February attempted to commit suicide by taking a large dose of arsenic, the exact quantity being unknown. The ingestion of the poison was followed by a severe attack of gastro-enteritis, and six weeks later the patient first noticed symptoms referable to the nervous system. There were at first numbness and pain in both feet, followed by a gradual loss of power until he was unable to stand. Later the arms and hands became affected in a similar manner. His symptoms persisted until the 1st of September, when he entered the Presbyterian Hospital. The pain is gradually diminishing. There is still a good deal of cutaneous anæsthesia, and he finds it difficult to pick up objects. There has been considerable atrophy of the muscles, especially of the interossei. He has a shuffling gait, dragging one foot after the other. The reactions of degeneration are obtainable in most of the muscles. No arsenic could be found in the man's urine at the time he entered the hospital.

The case was of interest, Dr. Thompson said, because the neuritis and atrophy had followed the ingestion of a single large dose of the poison, and because the man is evidently recovering. He is receiving the ordinary treatment, consisting of tonics and applications of electricity.

DR. ANDREW H. SMITH referred to a very similar case which had been under his observation about five years ago. The patient had taken the arsenic with suicidal intent. He developed a severe gastritis, and before he had recovered from this symptoms of neuritis appeared. The disease followed a long and severe course, and it was months before the patient was able to walk.

DR. GEORGE L. PEABODY also mentioned a similar case which he had seen at St. Luke's Hospital four or five years ago. The patient was a woman, who, after taking a single large dose of arsenic, developed a peripheral neuritis from which she recovered in time.

Recent Theories of Immunity, from the Clinical Standpoint.—DR. W. GILMAN THOMPSON read a paper upon this subject (see page 37).

DR. BEVERLEY ROBINSON said he could discuss this subject only from a clinical standpoint, not from a theoretical one. One point to which he desired to refer was the immunity from certain diseases, such as pneumonia or diphtheria, possessed by certain individuals. This difference in susceptibility to disease was sometimes found to a remarkable degree among members of the same family. The immunity possessed by certain individuals, the speaker said, was possibly due to the influence of heredity.

DR. ROBERT F. WEIR said that although this question of immunity entered into his domain only incidentally in his study of wound infection, he was hardly prepared, from his reading, to expect the conclusion enunciated by Dr. Thompson in regard to the low position to which the leucocytes should be relegated in the process of immunization. It is understood at present that so far as phagocytosis is concerned, the cells do not occupy the high position which they did formerly. That they do play an important part in the development of this immunity, however, most observers are agreed. The exhaustion theory and the saturation theory, which have been proposed to account for this immunity, are not satisfactory. The question is so complex that a perfectly convincing solution of it is yet to be attained. In our laboratory tests, an inoculation which may prove fatal under certain conditions may prove more or less harmless under altered conditions. Still, he would emphasize it as almost certain that the polynuclear cells provide the ammunition which destroys the germs primarily, and to a more or less permanent degree their toxins. In conclusion, Dr. Weir said that while there were still many points in connection with this subject which must be regarded as *sub judice*, the *résumé* embodied in the paper of Dr. Thompson was of great value.

DR. F. P. KINNICUTT said the exact mechanism of immunity, either natural or acquired, specific or general, must still be considered an unsolved mystery. Probably even the most enthusiastic bacteriologist will admit this. It is an interesting fact that in the injection of cholera embryos into the peritoneal cavity of protected animals we find an enormous number of dead embryos entirely outside the cells, which have been destroyed extracellularly. Again, when we inject antidiphtheritic serum and examine the faucial membranes, we find a vast number of bacilli that have been destroyed without any phagocytosis. Phagocytosis can be considered only as a phenomenon of natural resistance. In acquired immunity it is probable that the tissues and fluids are so affected that there are produced both antitoxic and germicidal porperties in them.

DR. ANDREW H. SMITH said that the theory of immunity most satisfactory to his mind was that of Pasteur, which is that there is an exhaustion of some material which is necessary to carry on the process which eventuates in the disease. The process of fermentation is the one most analogous to that embodied in this theory; when the sugar is exhausted, the fermentation ceases. We can add something that will prevent the fermentation from coming on—something that will stop the reaction between the ferment and the sugar. In this broad way, perhaps, the condition of immunity might be explained. The speaker said he could not understand how immunity could be explained on chemical principles, such as a change in the alkalinity of the blood. Why should such a change affect just one particular disease? For instance, if the patient has diphtheria and the alkalinity of the blood is changed, why should the diphtheritic material alone suffer? Why should it not act on the potentiality of any other infective disease as well?

A Series of Specimens Demonstrating Appendical Disease Prior to the Onset of Grave Attacks.—Dr. Robert Abbe exhibited a series of over fifty specimens demonstrating abnormal conditions of the appendix prior to the onset of grave attacks of appendicitis. The specimens were prepared by first distending them with alcohol, allowing them to harden, and then slicing them. They had been all removed from living subjects. While no two of these specimens, Dr. Abbe said, were alike, they all showed a strictured condition, more or less advanced. Many of the patients from whom these specimens had been removed gave a history of having had slight attacks of pain in the appendical region during the past two, five, ten, and even twenty years. During those periods probably the stricture process had been going on, and when such stricture becomes complete, then we have what is known as a frank attack of appendicitis. The latter, therefore, is really the climax of appendical disease and not a primary condition. In all the specimens shown by Dr. Abbe, the appendage had been removed before it became gangrenous or had ruptured. In some of the specimens the stricture was single; in others, multiple. In every instance in which the appendix contained a calculus, the latter was located behind the stricture. In only one instance was a foreign body—namely, a corn husk—found in the appendix; in the other cases the calculus consisted of exfoliated epithelium, which first forms a putty-like mass and then condenses into a small hard concretion, occupying the distal portion of the appendix. Dr. Abbe said the point he wished to emphasize was that latent appendicitis may exist for a number of years without giving rise to serious symptoms. The only symptoms of this condition may be slight occasional attacks of tenderness in the appendical region, or digestive derangement. In conclusion, the speaker said that in a large number of cases of appendicitis coming under his observation there was an antecedent history of grippe.

Dr. Weir said that the specimens shown by Dr. Abbe give a very clear demonstration of the pathology of the process which causes appendicitis. The speaker exhibited a number of colored casts, showing the appendix in various stages of stricture and gangrene.

A Case of Malignant Endocarditis.—Dr. J. W. Brannan reported this case. The patient was a coachman, fifty-three years old, who entered Bellevue Hospital on October 16, 1897. He had never had rheumatism or any serious illness up to the time he came to the hospital. About three weeks before his admission he began to cough, with moderate greenish expectoration. He had had no night sweats, but had lost about ten pounds in weight. His temperature when he was admitted was 103.8° F.; pulse, 108; respirations, 32 a minute. An examinaation disclosed some dulness over the base of the left lung posteriorly, with diminished respiratory sounds; there were a few râles scattered over both lungs. The heart was apparently normal. During the first two weeks after his admission the man did not seem to be very sick, in spite of the fact that his temperature ranged daily from 97.5° to 104.5° F. Repeated examinations of the sputum showed large numbers of streptococci and diplococci, but no tubercle bacilli. The blood was examined from time to time, and showed a varying amount of leucocytosis. The physical signs in the chest were limited to an area about three inches in diameter at the lower angle of the left scapula, at which point there were slight dulness and increased vocal fremitus, with distant bronchial breathing, voice, and whisper. The case was regarded as one of broncho-pneumonia due to streptococcus infection. The most marked symptom was the irregularity of the temperature, which frequently rose to 104.5° F., sometimes during the day and sometimes at night. A malarial element was suspected, but no plasmodia were found in the blood. The man was carefully and frequently examined, but there was no suspicion that he was suffering from any form of cardiac disease. The valvular sounds were normal throughout his illness. He gradually grew weaker, and died after he had been in the hospital about a month.

At the autopsy the lungs showed numerous areas of broncho-pneumonia, with one almost necrotic area in the left lung at the point referred to above. The left side of the heart was normal; on the right side the tricuspid valve was partially destroyed and was the seat of large vegetations. Streptococci were found in the lungs and various other organs, and also on the heart valves.

Dr. Brannan said that out of two hundred cases of malignant endocarditis on record he had found only nine in which the lesions were limited to the right side of the heart, as in this case.

Dr. Walter B. James, who had seen the patient and assisted at the autopsy, said the left lung showed a moderate amount of coagulation necrosis, with large numbers of streptococci, which were also present in the kidneys and in the vegetations on the tricuspid valves. Although the vegetations on these valves were very marked, yet they were so situated that they did not obstruct the flow of blood through the auriculo-ventricular opening, and this probably accounted for the fact that they gave rise to no murmur. The speaker expressed the opinion that the case was one of malignant endocarditis, with secondary pulmonary infection.

Dr. F. P. Kinnicutt said that a case very similar to the one reported by Dr. Brannan was observed in his service at the Presbyterian Hospital last winter. There was no heart murmur, and the diagnosis lay between typhoid, typhus, and malignant endocarditis. The patient died on the sixth day of his very acute illness, and at the autopsy a malignant endocarditis, confined to the right side of the heart, was found, with infarctions in the lungs and kidneys. The case was one of streptococcus infection. The speaker said that in cases of this character, he did not see how when there was no heart murmur a positive diagnosis could be made.

Dr. G. L. Peabody said he agreed with Dr. Kinnicutt that in a case of malignant endocarditis without a murmur, the diagnosis is difficult and perhaps even impossible. The possibility of that affection, however, should occur to one's mind in obscure cases of sepsis; but almost all of the members would probably admit, as he did, having failed to make the diagnosis in a considerable proportion of cases.

Dr. E. G. Janeway said he agreed with the previous speakers that it is a difficult matter to make the diagnosis of ulcerative endocarditis without a heart murmur, and yet it can sometimes be done. The presence of petechiæ or the occurrence of hemiplegia or of convulsions due to cerebral embolism may lead us to suspect that we have to deal with a case of malignant endocarditis. Such lesions sometimes exist in the mitral area without giving rise to a murmur, as they may cause no obstruction or regurgitation. Cases of ulcerative endocarditis may resemble remittent or typhoid fever, and *vice versa*; cases of remittent or typhoid fever may be mistaken for ulcerative endocarditis. Petechiæ may occur in the course of typhoid fever. Another point to be borne in mind is that the heart murmur in ulcerative endocarditis may disappear when the patient grows weak, or it may grow very faint after the patient has rested in the recumbent position for some time.

Dr. Kinnicutt said he had seen two cases of typhoid fever within the past year which were compli-

cated by the occurrence of petechiæ. One recovered: the other ended fatally. In the fatal case not only a very abundant petechial eruption was present but most profuse hemorrhages occurred from the nose, the gums, and the intestinal tract.

A Case of Bradycardia with Sudden Syncopal Attacks.—This case was reported by Dr. C. L. Dana. The patient, who had been under the care of Dr. Poucher, of Poughkeepsie, was a married man, fifty-two years old. He gave no history of any inherited heart or arterial disease. There was no history of syphilis; he did not use alcohol or tobacco. There was no rheumatic or gouty history. He had been in good health until the present illness, which began about two years before he had come under Dr. Dana's observation. He then had an attack of vertigo, followed by sudden syncope; he fell as though struck by lightning and remained unconscious for about thirty seconds, gradually recovering. Following that attack he remained in bed for several weeks on account of weakness, and during that period his pulse was found to average 40 per minute. Subsequent to this the man had similar attacks, sometimes four or five daily, sometimes as many as fifteen or twenty; these attacks either consisted of simple vertigo or they were accompanied by very sudden loss of consciousness. In some instances the attacks were preceded by an aura, which consisted of a flash of light before the eyes. The patient was seen by Dr. Dana in consultation with Dr. Poucher, in March, 1897. He was fairly well nourished. He showed no objective lesions connected with the nervous system or any other organs excepting the heart and arteries. The heart was somewhat enlarged, and there was a faint systolic murmur at the apex; the pulse was 36 per minute, regular, and of high tension. There was no nephritis. The patient was given at various times strychnine, glonoin, digitalis, and iodides, with careful attention to rest and food, but his attacks continued, and about six months later he died. During some of his later attacks Dr. Poucher found the pulse as low as 14 per minute. The autopsy was made by Dr. Poucher. He found the heart somewhat enlarged; the wall of the right auricle was quite thin and that of the right ventricle extremely so, almost like a piece of paper. Some calcareous deposits were found in the walls of the heart and on the tricuspid valves. No examination was made of the nervous system.

Dr. Dana said the case was particularly interesting because of the attacks of syncope which accompanied the bradycardia. They were not like ordinary fainting spells, but came on with lightning-like suddenness, which seems to be a peculiarity of such attacks in cases of permanent slow pulse. The bradycardia in these particular cases, the speaker said, is probably of nervous origin.

Dr. Janeway said he had seen a number of cases of bradycardia, but he had never succeeded in getting an autopsy. In one case, the patient's pulse averaged 28 per minute. In another case, in which there was aortic obstruction, the pulse sometimes ranged from 32 to 36 a minute for two or three weeks, and improved with rest in bed. The attacks in that case seemed to be brought on by fatigue and were associated with aortic trouble. In another case, that of a man aged seventy years, the pulse fell to 36 per minute, and remained so without giving rise to much discomfort.

Dr. H. F. Walker said that several years ago he met a man of remarkable vigor, who had never been ill, whose pulse habitually was 44 a minute. He afterward died of pneumonia. He had never suffered from attacks of syncope.

Dr. Robinson said that a number of years ago he had a man under his care whose pulse habitually ranged from 40 to 50, and who was subject to sudden attacks of syncope. His slow pulse rate was associated with great weakness and prostration.

Dr. Kinnicutt said that some time ago he reported a case of bradycardia associated with epileptiform attacks. At times the patient's pulse fell as low as 28 per minute. The bradycardia continued at intervals for a number of years, the patient finally dying of some intercurrent disease.

Dr. Thompson said that in three or four recent cases of bradycardia which he had seen there were no attacks of syncope. The most pronounced case was that of a man, sixty years old, whose pulse for a number of consecutive weeks did not go above 28 and frequently fell as low as 18 or 20 a minute. The man was well nourished and declared that he had known of his slow pulse for two years. He never had any fainting-attacks and appeared to enjoy excellent health. There was no demonstrable abnormality of the heart and no murmur. This man was lost sight of. Another case was that of a man, twenty-four years old, who had a pulse of 44 a minute. He had never had any attacks of syncope. His heart appeared normal and his general health was excellent.

Dr. Dana, in closing, said he did not wish to give the impression by his remarks that sudden attacks of syncope were necessarily associated with bradycardia, but rather that when such attacks did occur with bradycardia they indicated that the cardiac symptom was of nervous origin and not due to a structural lesion of the heart itself. Bradycardia might be the result of a number of different conditions, but this type which was associated with very sudden attacks of syncope seemed to be distinct, and probably depended on some lesion involving the pneumogastric nerve.

Dr. Janeway called attention to the fact that in the case reported by Dr. Dana the autopsy showed that the walls of the right heart were extremely thin.

Dr. Dana replied that equally thin walls had often been noted without the patient having sudden syncope.

The Widal Test.—In an editorial comment upon this test for typhoid fever the London *Lancet* says experience has taught that its value is not nearly so great as was predicted. The reaction is frequently not to be obtained until other signs place the diagnosis out of the realm of doubt. The test seems likely to have the same fate as the diazo reaction, of which so much was at first expected.

A New Splint for Fractures of Nasal Bones.—A No. 15 spring brass wire is bent into the form of a rectangular letter U, the arms of which are about one inch apart and long enough to extend from the upper lip to the crown of the head or beyond. Opposite the supra-orbital ridge a sharp angle is formed which enables the splint to enter the orbital cavity just below the orbital ridge; this angle fixes the splint against the supra-orbital ridge. The lower or transverse portion is carried forward away from the lip, for a distance of half an inch. Compresses placed between the splint and the side of the nose will correct deviations. If needed, a silk suture may be passed through the septum of the nose and tied to the transverse portion of the splint. For drawing down and firmly holding the point of the nose or its alæ this is the best appliance. If one wishes, he can add to the intranasal splint an intranasal wire, which should be covered with soft-rubber tubing. The splint is held in position by means of a strip of rubber adhesive plaster passing over the forehead and around the back of the head, like a hatband. The advantages of the splint are that it is simple, easily made and applied, and permits inspection of the nose without removing the apparatus.—Hawes.

PRINCE OF WALES' FUND—IMPORTANT SPEECH BY THE PRINCE ON HOSPITAL MANAGEMENT AND FINANCE—SIR HENRY BURDETT'S SCHEME TO ENLIST CHILDREN FOR HOSPITAL FINANCES—MAIDSTONE—PROFESSOR MACEWEN—ROYAL BRITISH NURSES—DEATHS OF TWO AGED VETERANS—EXPLOSION IN A CHEMICAL FACTORY.

London, December 24, 1897.

This being Christmas week, social functions are pushing medical matters into the background. Some excitement is experienced in the hospitals, where the residents and others are decorating and getting up amusements for the patients who are well enough to pay attention to them.

On Monday the Prince of Wales presided over a meeting of the council of his hospital fund, when Lord Rothschild, as treasurer, made a financial statement. The amount in the bank was stated as £180,000, of which £99,000 is invested. It is expected that the hospital stamps initiated by the *Daily Mail* will bring in from £38,000 to £40,000. The prince, who seems to have a firm grasp of the hospital question, said he was anxious to spend all the income, but would reluctantly part with the capital. At the same time he was willing to use the amount from stamps, as that was something apart from other sources and intended as for the jubilee year. He recognized that what another year might produce was problematical, and partly dependent on the use made of this year's income. His own view was that full inquiry should be made in every case before granting assistance, so that all sums should be wisely spent. "Unfortunately," continued His Royal Highness, "as you must be well aware, in many cases wings and wards are now built when the hospitals can only hope that future charity by means of dinners and bazaars may give them the pecuniary assistance necessary to defray expenses; and if they do not receive as much money as the managers hope from these bazaars and dinners they are ultimately obliged to close the very wards which they recently opened. It is this extravagance in the maintenance of hospitals which this fund should endeavor to discourage." The prince's speech has given much satisfaction; so has the decision arrived at by the meeting, that in view of the controversial character of the proposal of the Charity Organization Society for a central hospital board it is not expedient for the prince's fund to be associated with the movement. If the prince's fund is kept equally clear of the Sunday and Saturday funds, it will secure more confidence than either. The mistakes of the Saturday and the prejudices of the Sunday funds need not be repeated. With regard to the former, it has been decided to discontinue the street collection, which was so objectionable.

Sir H. Burdett is doing his utmost to create a boom for his hospital stamp albums. He wants all the children to have these albums instead of Christmas presents, and a number of society people are supporting him. It is proposed also to send them out in place of Christmas cards, but it is doubtful if they will displace that growing industry. There is an enormous capital invested in it, and thousands of designers and printers find employment in it. Sir Henry has got photographers to give a free portrait to every child who will go for a sitting and put his or her portrait in the album. It is hoped to enlist the infant of the Duke of York in the plan. Medical men look rather askance at Sir Henry's scheme, from the fear that it may increase hospital abuse and give the owner of a shilling's work of stamps a notion that he has purchased a right to free treatment at the hospitals.

The epidemic at Maidstone is not quite over. Five more cases have been notified since I reported, bringing the total up to eighteen hundred and ninety. The official inquiry is expected to begin in January. The town council wishes to restrict the inquiry to the cause of the epidemic, but the water company desires all matters to be dealt with, in the hope that drainage and other defects may be held to share the blame.

I am glad to hear that the difficulty at the Glasgow Infirmary is being arranged, and that Dr. Macewen will be able to retain the ward which it was proposed to transfer to other purposes.

The Royal British Nurses' Association has had another stormy meeting. A small minority opposed the new code of bylaws in a manner scarcely to be expected with the Princess Christian in the chair. It was hinted that the privy council would not sanction the changes in rules which were so obnoxious to some. The minority declares that nurses ought to be left to manage their own affairs—though the last two meetings do not say much for their capacity to do so. Certainly the doctors who have tried to help them have found no gratitude, and the wonder is that they consent to take further trouble in the matter.

The death is announced of Deputy Inspector-General of Hospitals James Kellie, in his ninety-second year. He retired from the Madras army in 1859.

The death is also announced of the senior coroner in England, Dr. Henry Churton, who held that office for Birkenhead. He had reached the age of eighty-four.

A young chemist was killed the other day by an explosion of erythrol tetranitrate, which he was manipulating to make tablets.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE NEW HEALTH LAW—THE LATE PROFESSOR TARNIER—INAUGURATION OF HOSPITAL BOUCICAUT—PROFESSOR ROBIN AND VENESECTION—PHLEBOTOMY IN URÆMIC INTOXICATION.

Paris, December 23, 1897.

The French authorities are just giving another evidence of their zeal in looking after the health of their citizens. To be precise, the senate has taken up the discussion of a law having for its object the protection of the public health. Drs. Brouardel and Cornil are its framers, and it cannot be otherwise than productive of great good from a sanitary point of view.

This law has one especial characteristic, and that is, it defines exactly the powers of the municipal as well as those of the prefectural authorities in questions of sanitation—not only determining the sanitary measures to be taken in cases of endemic or epidemic diseases, but obliging the communes to conform without delay to the regulations on public hygiene. And this is a trouble with laws in our own country. How frequently do we not see the State and city authorities clashing in matters of quarantine, sanitation, and others touching the public health. It is here that politics and bureaucracy or red tape interfere often very seriously with the execution of an essentially good law, to the detriment and inconvenience of the public for whose protection against disease it was made. The new French law is in sum as follows: When the sanitary condition of a commune requires bettering—especially when a commune is not provided

with drinking-water of good quality or in sufficient quantity, or when the waters used remain stagnant in the midst of habitations—the prefect, upon the report of the sanitary inspector having been previously communicated to the municipal council, shall invite the council of the department or county to deliberate upon the utility and nature of the work judged necessary; the mayor shall be prepared to present the observations to the council of hygiene of the department. In case of an opinion contrary to the execution of the works or demands on the side of the commune, the prefect shall transmit the deliberation of the council to the minister of the interior, who shall, if he sees fit, submit the question to the consultative committee of public hygiene of France. If, at the expiration of three months, no measures have been taken regarding the execution of the works, a decree of the president of the republic, given in a council of State, shall order their execution.

These measures and others analogous will assure, in a much larger measure than exists to-day, the protection of the public health.

A tribute has been paid by the Academy of Medicine to the memory of the late Professor Tarnier, who had been its president. Before adjourning its sitting as a mark of respect, the academy had previously listened to the oration, so simple and so just, pronounced by Professor Budin, the accoucheur of the Maternité, at the obsequies of his old master. It has also been decided that the clinic of accouchements shall in future be known as and called the Clinique Tarnier. Moreover, it is probable that the municipal council of Paris will accede to the wishes expressed the other day by the medical collaborator of *Figaro*, in giving to a street of Paris near the Maternité the name of this great physician, thanks to whom the mortality of women in childbirth has fallen from ninety in one thousand to one-half in one thousand.

The Hospital Boucicaut has been at last formally and officially inaugurated, and M. Felix Faure, president of the republic, was there with a numerous cortege. This hospital, which is considered one of the finest in Paris, and is now functioning, consists of eight pavilions, resembling each other exteriorly as regards the style of architecture. Four of the pavilions are reserved for medicine, two for surgery, and two for lying-in and obstetrical cases. Three other pavilions of different forms are assigned as follows: the first to external consultations; the second to the administration; the third, which is the prettiest of all, is to be the rendezvous for patients of the Bon Marché, for whom twenty-one beds are reserved. A bust of Madame Boucicaut, in the middle of a pretty garden before the Bon Marché pavilion, will serve to remind visitors that she was the founder of this magnificent hospital, and that of the millions she left many were devoted to the relief of human misery and suffering. Beauty has been made quite a prominent feature, and it seems to have been realized that the pleasure of the eyes aids the cure and makes convalescence the shorter.

Dr. Albert Robin, the savant professeur at the Hospital de la Pitié, has just given us the practical results of his studies in bleeding, which throw a new light upon a time-honored therapeutic procedure. The conclusions he reaches are these: "Beside the depletive action of bleeding already known, there is another not sufficiently put in relief, namely, that which favors oxidation, thanks to the superactivity that it gives to nutrition."

Venesections are therefore a powerful agent to employ against diseases accompanied by decline of the nutrition or slackening of the oxidations, and not as a means in a given disease or a particular morbid entity. Bleeding has consequently, in Dr. Robin's opinion, a double action mechanical and chemical. The diseases in which he has recently bled were cerebral hemorrhage with ventricular inundation, acute nephritis with uræmic respiration, saturnine Bright's disease with epileptiform crises and enormous dyspnœa, cardiac asystolia with cyanosis, uræmic coma with left hemiplegia, uræmic dyspnœa with hydrothorax, asystolic aortic insufficiency and pulmonary congestion, arterio-sclerosis with mitral lesion; as well as others with œdema, anasarca, and dyspnœa. The quantity of blood taken varied from one hundred and fifty to two hundred and fifty and three hundred grams—in some instances with rapid relief. Of fourteen cases treated by bleeding, ten gave good results, and in four the treatment was not successful. These clinical examples confirm what has been ascertained by experimentation. It is true, however, that bleeding has been abused; but it should not on that account be made to disappear from therapeutics altogether.

Phlebotomy is advocated by Lépine and Bouchard in uræmic intoxication. They attribute that complication to the potassium salts contained in the blood. It is not so much the quantity of potassium salts taken away by bleeding, as the oxidation that follows, that is efficacious.

"SPONTANEOUS" FRACTURE OF THE CLAVICLE.

To the Editor of the Medical Record.

Sir: The "Somewhat Unique Case of Spontaneous Fracture of the Clavicle," reported in the Medical Record, December 25th, by Dr. T. H. Manley, of this city, is so unique as to justify one in making a query and also a suggestion.

That a man, thirty-four years old, in good health, should retire at eleven o'clock at night and wake up at 3 A.M. with a fractured clavicle, is indeed mysterious; is, in fact, a rather flagrant violation of the laws of nature.

His occupation, that of a billiard player, calls at times for rather active exercise on the left side, such as springing on or off the edge of the table. We are told that he was not addicted to "excesses" of liquor.

Did he at any time from four hours to seven days previous to discovery of the fracture "sprain" his shoulder, indulge in any severe exercise, or in skylarking? It is very easy for the average dispensary patient to forget a knock or bruise.

A person may have a fracture of the clavicle following a rather slight injury, without deformity and without pain. Such a fracture, being either incomplete or subperiosteal, may very easily become complete with sudden onset of pain and the typical deformity. I have also seen fracture of the clavicle with slight overriding, no pain and no dropping of the shoulder, causing the patient slight or no discomfort.

We should consider Dr. Manley's case as one of more or less complete fracture of the left clavicle, rendered complete by the patient rolling over on his left shoulder. This conclusion is all the more reasonable, as it seems there is not a case on record of spontaneous fracture of the clavicle—Dr. Manley, in his report, stating: "In an examination of the literature on fractures by American and foreign authors, I am unable to find a record of any similar case."

James Porter Fiske, M.D.

[illegible] West Forty-Seventh Street.

Malarial Fever is said to be now unusually prevalent in the lower Mississippi Valley on account of the subsidence of the great floods.

Therapeutic Hints.

Strophanthus.—In a clinical study of this drug Dr. Reynold W. Wilcox (*The American Journal of the Medical Sciences*, May) summarizes as follows: "We may say that success in the administration of strophanthus requires: 1. An active, well-made preparation from a reliable source. 2. Avoidance of its use in fully or overcompensated hearts, in those which present advanced muscular degeneration or mechanical defects of high degree. 3. The use of not too large or too frequently repeated doses. From my own observations, the dose of five drops of a reliable tincture three or possibly four times a day is sufficient. In conclusion, I believe that, considering the limitations just enumerated, strophanthus is the drug of choice in: 1. All cases in which we wish to establish compensation. 2. All cases of arterial degeneration in which a remedy which causes more energetic cardiac contractions is required. 3. All cases of cardiac disease when diuresis is necessary. 4. All cases of weak or irritable hearts. 5. All cases of cardiac disease in childhood or old age."

A New Local Anæsthetic.—Orthoform, a white odorless powder slightly soluble in water, anæsthetizes when brought into contact with nerves, as in burns, ulcers, etc., or when used on mucous membranes. It is antiseptic, and has given good results in gastric ulcer and carcinoma. For internal use a soluble acid salt is used. It is said to be non-poisonous and non-hygroscopic.—*Münchener med. Wochens.*, August 24, 1897.

Guaiacol.—This is the active principle of creosote. The latter itself is not a definite product, but a mixture containing, along with guaiacol, toxic cresols and toxic derivatives of pyrogallol. Liquid guaiacol is never quite pure, as it contains only seventy-five per cent. of the pure substance. Chemically pure guaiacol is a pharmaceutical possibility, but, like all the phenols, it is too irritating to be used except in very small doses. Moreover, it has an offensive odor and a burning, bitter taste.—James E. Newcomb.

Gastric Ulcer.—Rest in bed, hot poultices, Carlsbad water. The poultices should be very hot and changed every ten minutes. The pain disappears in about five days; then Priessnitz bandages should be substituted for the hot poultices. Strict regulation of the diet. Surgical treatment should be resorted to under the following circumstances: 1. When there are repeated hemorrhages which make the patient anæmic. It depends on the nature of the individual case whether an operation should be performed or not when there has been only a simple profuse hemorrhage, for it may be so abundant that surgical aid comes too late. On the other hand, patients often recover from the acute anæmia caused by a single hemorrhage. 2. When long-continued medical treatment has proved ineffectual to relieve the pains, gastro-enterostomy may be tried. 3. When there is perigastritis caused by adhesion of the stomach to other organs, especially when a subphrenic abscess has formed. 4. When there are perforation of the ulcer and an opening into the abdominal cavity. The chances of a perforated ulcer healing are of course very small.—Professor von Leube.

Bilious Headaches.—In all cases of sick headache there seem to be two factors: the general condition of the body and the local cause determining the pain to the head rather than to any other part of the body. One of the most common of the local factors is disturbances of the eyesight. I should say in nineteen cases out of every twenty—perhaps I ought to say in forty-nine out of fifty—the exciting cause of so-called bilious headaches is irregular vision due either to inequality of the two eyes or to astigmatism.—T. Lauder Brunton, "Lectures on the Action of Medicines," p. 167.

Surgical Suggestions.

Rectal Fistula.—The following important points should be observed: 1. A careful physical examination of the lungs as well as of the entire rectum is to be made in every case. 2. Pulmonary tuberculosis is not necessarily a contraindication. 3. Do not put down the knife until certain that every sinus has been divided. 4. Remove all diseased tissue. Large wounds are not to be feared. 5. Caution: the sphincter is to be divided only once and at right angles. 6. Special attention is to be given to the mucous opening. 7. Invasion of the perineum must be avoided, especially in females. 8. Systematic antisepsis is necessary if good results are desired. 9. Care and patience are required in the after-treatment. Dressings are not to be left to the family nurse. 10. In the after-treatment two warnings are to be heeded: complaints of unusual pain by the patient and increase of the discharge. Either of these may mean the formation of another abscess. 11. Hemorrhage and incontinence of fæces are the chief danger. Both are amenable to treatment and should not deter from the operation.—Cooke, *Medical News*, November 21, 1896.

Golden Rules.—The following suggestions in abdominal surgery are said to come from a celebrated London surgeon: Always avoid purgatives in treating a patient who has swallowed a foreign body. Give opium and constipating food—boiled eggs, cheese, puddings, potatoes, etc. Never close any wound of the abdominal wall till all hemorrhage has ceased. Never, under any circumstances, apply pressure to a wound of the abdominal wall to arrest hemorrhage. Never mind increasing a superficial wound of the abdomen in order to remove a foreign body or to secure a bleeding point. Never probe any wound in the abdominal wall. Never forget that all abscesses of the abdominal wall should be opened freely and at once. Never hesitate or delay to open and drain an abscess in the loin due to rupture or injury to the kidney. Never procrastinate in strangulated hernia. It is not usually the operation which will prove unsuccessful in herniotomy; the danger lies in your allowing the bowel to become irrecoverable. Never be deceived by an opiate masking the acute symptoms of hernia, obstruction, peritonitis. Never tap a suspected renal tumor through the abdominal parietes, *i.e.*, through the peritoneum. Always relax the abdominal wall after suturing. Never ligate *en masse* in cutting off omentum; do it piecemeal; the constricted edge of the apron of omentum may unravel, and fatal hemorrhage result. In protrusion of the viscera never neglect to pass your finger fairly through the wound to make sure that the reduction has been complete. And be careful never to push the bowel into an interstice between the muscle or into subperitoneal tissue.

Acute Osteomyelitis.—Rapidly increasing pain in an arm or leg, accompanied by swelling without redness or fluctuation, together with high fever and chills, is a typical picture. This is one of the emergencies of surgery. Free incision to the bone with chiselling into its marrow should be at once performed. There is no pus, as a rule, in early cases, but the periosteum is easily peeled from the bone. Timely operation

prevents necrosis. Any bone may be the seat of osteomyelitis, but it is commonest in the long bones.—*International Surgical Journal.*

Suppurating Wounds should not be packed so as to occlude the opening or impede the flow. A narrow strip of gauze passed well down to the bottom and loosely bunched about the external opening will serve every purpose of drainage.

Treatment of Spasmodic Lockjaw.—Woman, aged twenty-eight, for years suffering from firm closure of the jaws, varying in degree from day to day, but gradually getting worse. The temporo-maxillary joint and a displaced cartilage were excised, with benefit lasting only for two or three days: other methods of treatment failed. At last, after one each of the insertions of the masseter and the temporal and internal pterygoids were detached, the spasms disappeared and remained absent for six years, when they returned, necessitating a similar operation.—Kocher, *La Sem. Méd.*, December 18, 1896.

Fractures of the Base of the Skull.—I have seen such cases recover, although some days later I have been aware that there had really been a fracture, and for this reason: The fracture may run through the temporal bone and involve in some way the aqueductus Fallopii, through which the facial nerve passes, and the proof of the fracture having occurred is that ten days or so afterward the patient has paralysis on that side of his face. The fissure, if it runs through the temporal bone, becomes repaired, and repair may occur with an excess of callus which causes compression of the facial nerve in the canal and produces paralysis. In another fortnight, when the callus is absorbed, the nerve resumes its function and the patient gets well.—Heath, *The Clinical Journal*, June 16th.

To Prevent Disagreeable After-Effects of Chloroform and Ether Narcosis.—

℞ Morphin. hydrochlor. ..... gr. ii¼.
Atropin. sulph. ..... gr. ¼.
Chloral. hydrat ..... gr. iii¾.
Aq. dest. ..... ʒ iij.
M. S. Give ♏ xxiv. hypodermatically a few minutes preceding the administration of the anæsthetic.

Do not use this mixture in cases of heart lesion.—Fraenkel.

Abscess of the Liver.—The exploring needle is unreliable in finding small abscesses, and the use of the knife is recommended even though the needle fails to locate the abscess to which the symptoms point.—John O'Conor.

Dislocation of the Semilunar Cartilage.—The lesion is always caused by traumatism; it is the result of exaggerated flexion with either external or internal rotation; the inner cartilage is most often displaced; the anterior end is more apt to be dislocated than the posterior; the symptoms may be reduced to localized pain; the author prefers Croft's method (arthrotomy with ablation of the disc) to meniscopexy, as practised by Annandale; arthrotomy has given the most complete cures without any deaths.—Rosa.

Cholecystotomy.—The indications for operation are: 1. Infrequently recurring biliary colic without jaundice and with or without enlargement of the gall bladder. 2. In enlargement of the gall bladder without jaundice, even if unaccompanied by great pain. 3. In persistent jaundice ushered in by pain and when recurrent pains with or without ague-like paroxysms render it possible that the cause is gall stones in the common duct. 4. In empyema of the gall bladder 5. In peritonitis starting in the right hypochondrium. 6. In abscess around the gall bladder or bile ducts, whether in the liver, under the liver, or over the liver. 7. In some cases when, although gall stones may have passed, adhesions remain and prove a source of pain and illness. 8. In mucous, muco-purulent, or biliary fistula. 9. In certain cases of chronic jaundice, with distended gall bladder dependent on some obstruction in the common duct, although the suspicion of malignancy be entertained. In such cases the increased risk must be borne in mind, as malignant disease may be the cause of the obstruction, and operation in such cases is attended with greater danger than ordinarily. 10. In phlegmonous cholecystitis and in gangrene, if the case has been seen and recognized at a sufficiently early stage of the disease. 11. In gunshot injury or in stab wounds over the region of the gall bladder. 12. In suspected rupture of the gall bladder without external wound. 13. In some cases of chronic catarrh of the gall bladder or bile ducts. 14. In suppurative cholangitis.—Mayo Robson.

Injections of Alcohol in Carcinoma.—Alcohol favors cicatrization in all growths like struma, angioma, cysts, lymphatic-gland tumors, sarcoma, carcinoma, and especially carcinoma of the breast and cervix uteri. Under its use, in fifteen out of eighteen cases of carcinoma of the breast, the growth gradually dwindled away, until in a year there was nothing left but the connective-tissue stroma, and there has been no return. Five cases of carcinoma of the cervix also recovered completely, and the patients are still living and in good health. The effect on the general health is even more surprising. The pains and uneasiness pass away, and sleep, appetite, assimilation, and strength return in a most remarkable manner.—Hassel.

Tonsil Tumor.—A recently developed unilateral non-inflammatory new formation in a subject past middle life is suggestive of malignancy, especially if the growth is hard, dense, and of rapid progress.—Newman.

Pruritus Ani.—

℞ Menthol 4
Alcohol 30
Distilled water 60
Dilute acetic acid 15
For external use only.
℞ Carbolic acid 5
Hydrated potash 2
Linseed oil 30
Bergamot oil ..... q.s.
Apply at bedtime.

In very severe cases deep cauterization of the parts with nitrate of silver or the thermo-cautery may be employed. Section of the nerves gives good results in pruritus of the anus, vulva, and scrotum, when the affection is very intense.—Cumston.

Acute Cystitis.—A very frequent cause of acute cystitis is the decomposition of residual urine. This may quite readily be cured without washing the bladder and without internal medication, simply by drawing off every drop of urine by the catheter every three hours. The catheterization must be done punctually every three hours, day and night, whether the patient urinates or not. Five minims of the oil of wintergreen twice daily, and the ingestion of a gallon of water every twenty-four hours, will contribute to the cure and will greatly hasten it.—*International Journal of Surgery.*

Hemorrhage in Brain Surgery.—For arresting bleeding from the diploe use Horsley's antiseptic wax. As regards the dura, if it be found necessary

to ligate a vessel in its continuity, this is best done by passing a small semicircular Hagedorn needle, armed with fine silk or catgut, round it, care being taken to avoid injury of the subjacent brain and cerebral veins. When an artery bleeds in the divided dura it may be seized with forceps and ligatured; veins are best secured by an armed needle being passed round them, as the forceps are apt to lacerate and tear the vessel. This is also true of cerebral veins.—KEEN.

In Shock following abdominal operations, the following axiom is laid down: When a patient is put back to bed with a pulse of 140 and the heart shows no tendency to quiet down in twenty-four hours, the patient almost invariably dies, apparently from prolonged shock.—KEITH.

Obstruction of the Large Intestine most commonly takes a chronic course (as an exception to this must be mentioned volvulus of the sigmoid flexure). The pain is not so intense. Vomiting is late to appear, is scanty, may diminish, and is rarely feculent until after a considerable interval. Meteorism appears early, and is apt to be marked.—FREDERICK TREVES.

New Instruments.

A NEEDLE FOR THE REPAIR OF THE CERVIX UTERI.

BY FRANK H. CLARK, M.D.,

BROOKLYN, N. Y.

ONE of the ever-present annoyances attending the operation of trachelorrhaphy, in my experience as well as in that of others with whom I have been associated in the past few years, seems to have been the selection of the needle best adapted to the liking of the operator and the needs of the work in hand. If the cervix to be repaired be thickened or hypertrophied, the needle used must be long enough to transfix both lips fairly to insure correct approximation, or else the operator must introduce his needle through each lip separately, which necessitates the catching and uncatching of needle forceps at least twice. If the needle is long, its butt is constantly engaged in the more or less lax vaginal tissues, thus preventing the necessary sweep of the forceps required to place the sutures in the proper positions.

Then, again, the style of needle is a question of some importance—one preferring a short, straight article, with or without a cutting edge; another will select a full-curved, round, pointed needle; while still a third will elect to use a half-curve, twist, or something else to his fancy. Whatever needle is used, however, is subject to the annoyances noted, which are worthy of notice from the fact that they consume a deal of time, and time is of great importance when a patient is under an anæsthetic.

With the object of relieving the operator of the usual embarrassments consequent upon the use of the various needles in vogue, I have had Messrs. Haslam & Co., of Brooklyn, make for me a needle which at this time seems to answer every purpose and do the necessary work in less than half the time required by the use of separate needles. Its construction is so simple that a glance at the cut is sufficient to note its character as well as its mode of operation.

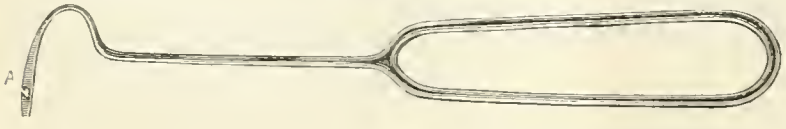

FIG. 1.

Perhaps a word, however, relative to its use may be *à propos*. The parts having been properly denuded and brought into view by means of volsellum forceps and approximated, the operator transfixes both lips of the cervix close up to the angle, and, depressing the handle of the instrument, brings the point of the needle toward him, thus exposing the open eye, into which an assistant immediately places a suture, holding lightly the short end, which is drawn through the parts as the needle is withdrawn. The suture is at once tied, and a second placed in the same manner.

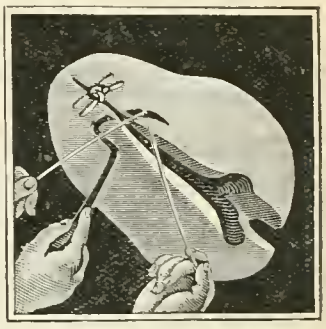

FIG. 2.

By this means I have introduced six sutures and tied them in less time than it usually takes to place two. Hence the amount of time and labor saved is obvious. Several physicians who have tried this little instrument have pronounced it as highly satisfactory.

A glance at the cut presented will at once make its mode of operation clear to the most casual observer.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 8, 1898:

	Cases.	Deaths.
Tuberculosis	128	126
Typhoid fever	15	1
Scarlet fever	222	24
Measles	398	13
Diphtheria	182	21
Laryngeal diphtheria (croup)	6	0
Chicken-pox	36	0
Cerebro-spinal meningitis	0	3
Small-pox	1	0
Erysipelas	1	0

Alcohol Consumption in the United States.—A gratifying sign of the times, and one which should give us great encouragement, is the marked decline in the consumption of alcohol throughout the world. It has been greater in America than elsewhere, and since 1888 amounts to about thirty per cent., nearly one-third. That is, as compared with 1888, the total consumption of alcohol in the United States in 1896 is one gallon *per capita* less. Think, a moment, what this means. There are 70,000,000 population in the United States. That indicates that 70,000,000 gallons of alcohol less was consumed in 1896 than in 1888. Suppose that there is one man to every seven of the population. It means that each man drank in 1896 seven gallons less than formerly. It means that 70,000,000 gallons of alcohol (absolute, "proof spirit," from which liquors are made, diluted), at, say, $2 per gallon, represents a saving on this commodity of $140,000,000, a sum sufficient to build thirty granite palaces like the capitol at Austin; a sum sufficient to

support every Christian minister in the world.—Dr. F. E. Daniel, *Texas Medical Journal*, November, 1897.

A Curious Origin of Phosphorus Poisoning.—Dr. Delobel relates, in the *Gazette Méd. de Paris*, November 20th, the history of a shoemaker who developed necrosis of the superior maxillary bones, due indirectly to the habit of smoking. Many cigars were consumed daily, and in such a manner that the butt required frequent relighting. The matches thus used exceeded one hundred daily, each giving off a certain amount of the vapors of phosphorus to be inhaled.

When Called to a case to supplant a brother practitioner, do you inquire whether his fees have been paid him in full to date of discharge? This is one of the ways of securing for the profession of medicine the respect which is so richly deserved but so rapidly disappearing.

Kaiserling's Method for the Preservation of Specimens with their Natural Colors.—Slices of organs from 3-5 cm. thick are placed for from three to five days in—

1. Formalin	200 c.c.
Aq.	1,000 c.c.
Nitrate of potassium	15 gm.
Acetate of potassium	30 gm.

They are then removed, the fluid is allowed to drain off, and are placed in—

2. Alcohol 80% for 6 hours, then
" 95% for 2 hours.

From this directly into—

3. Aq	2,000
Acetate of potassium	200
Glycerin	400

for permanent preservation in a dark place. Further details for the preservation of whole organs, etc., should be studied in the original article (C. Kaiserling, *Virch. Arch.*, Bd. 147, S. 389). The results thus obtained are certainly wonderful and promise to be one of the greatest of this generation's aids to teaching. —*Journal of the Boston Society of Medical Sciences*, March, 1897.

Roman Table Manners.—If any of you have been to Rome you will have seen in the palace of the Cæsars a small room adjoining the banqueting-hall; this is pointed out as being the place in which the Romans used to empty their stomachs when they had eaten so much they could eat no more. Then, having emptied their stomachs, they went back and finished the feast. In these Roman feasts the food was admirable in regard to quality, and was objectionable only in regard to quantity.—T. Lauder Brunton, "Lectures on the Action of Medicines," p. 399.

Leprosy in Constantinople.—Dr. Zambaco (*Lyon Médicale*, August 29, 1897) does not think leprosy contagious. He relates that more than four hundred lepers circulate freely in the streets of Constantinople and are engaged in all kinds of trades, yet they do not appear to give the disease to the inhabitants of that city. Among these four hundred lepers some have come from the regions of the Turkish empire, where leprosy always exists, and others are Spanish Israelites who have settled there since the time of the Inquisition in Spain.

Bellevue's Early History.—Mr. Robert Lenox, in behalf of the board, concluded the purchase in 1794. This plot was about five acres in extent, and had been once a part of the Kip's Bay Farm. It was conveyed by Jacobus Kip about the year 1765 to Peter Keteltas, by him to Martin Hoffman, and by him in turn to Robert Leake. In 1772 Leake gave to the place the name of Belle View. In 1781 it was again sold, and in 1783 it came into the possession of Lindley Murray. The latter gentleman, while residing in England in 1793, whither he had retired at the close of the war of independence, conveyed this property through his attorneys to Mr. Brockholst Livingston, who retained the name, but with a different spelling —Belle Vue—and this is the genealogy of the name. —Carlisle's "History of Bellevue."

Thermometers.—Not until 1603, when the researches of Sanctorius gave to the world her first thermometer, did the study of bodily heat become more than a subject of guesswork. As a matter of course, Hippocrates recognized the variations of surface heat in health and disease, but it was with him, as with many of his successors, a mere matter of the laying on of hands.—Dr. Mark A. Brown.

Insomnia Cured.—It is a matter of record that more than one New Yorker has been cured of insomnia on listening to the prosy stories to be heard in a certain club in Washington. I may quote the simple and trite observation of the sable Virginian who fetches my breakfast, which led him to remark, in contrasting this with other cities he has visited, that "every day here 'pears like Sunday, even after coming from a place like Philadelphia."—Dr. Irving C. Rosse, *The Atlantic Medical Weekly*, August 21st.

In Moscow physicians are paid from three to five roubles for ordinary visits; this is equivalent to $1.55 to $2.60. All visiting as well as resident surgeons and physicians to hospitals are paid moderate salaries. —*New Orleans Medical Journal.*

In Paris the physicians have sufficient sense of the proper mutual protection which is their right to publish a "black book" containing the names of would-be swindlers, and to refuse attendance upon those who treat medical men disgracefully. Inhumanity cannot be brought forward as an argument in a large city well supplied with public charities, night service, quick ambulance system, and all other means of succor for those too poor or too mean to pay a doctor's fee.

Photographs of Authors.—Some of our exchanges are making quite a specialty of publishing the photograph of each author with his communication. Some of these authors have been known to us through their writings for many years, and we regret exceedingly that they have consented to this new departure of things. A young acquaintance of ours once operated on an old gentleman for double cataract. When sight had been restored, out of the thankfulness of his heart our aged friend called for the surgeon who had given him back his sight. Upon looking at the countenance (anything but prepossessing) which appeared before him, he exclaimed: "Lucky for you, young man, I did not see you before you operated, or I would never have given my consent." We are bound to exclaim in some of these recent cases that our opinion of the value of some of these contributions has greatly changed since we have gazed upon the oil-soaked hair, the waxed mustache, and the sickening smile which too plainly says, "Don't you think I'm sweet?"—*The Medical Review.*

Vital Statistics in Russia.—The natural increase of the population is kept down to a relatively low figure by an abnormally large death rate, which is mainly due to avoidable causes. Infectious diseases and insufficiency of medical help are among the most obvious. A few years ago it was stated by the Russian medical department that in the Caucasus there was

but one hospital for 309,000 persons and one bed for 12,000. In no country in the world are infectious diseases so frequently mortal as in Russia. Children especially suffer, and diphtheria, measles, scarlatina, small-pox literally decimate villages and country towns. It has been stated by the statistician Ekk, with the help of official figures, that about 1,900,000, chiefly children, die every year, who might with a little more care be preserved to the empire.—*Contemporary Review.*

Vaccination in Japan.—In 1870 Japan was visited by a terrible epidemic of small-pox, which almost decimated Yokhama. Vaccination was made compulsory in 1896. The Japanese are said to have been struck with the fact that pockmarked foreigners were rarely seen in Japan.

Chloroform in Obstetrics.—In a paper read before the Obstetrical Society of Boston, Davis (*Boston Medical and Surgical Journal*, August 22, 1897, p. 193) expresses the conclusion that the most recent experimental study indicates that the evil effects of chloroform result from vasomotor paralysis, causing the accumulation of blood in the abdominal viscera and bringing about partial or complete cessation of function in the nerve centres from acute anæmia. Pregnancy increases vasomotor tension and thereby renders the pregnant woman less liable to the injurious effect of chloroform. In normal labor the actual expulsion of the child may be safely rendered painless, dilatation of the birth canal furthered, and laceration diminished by light and transient narcosis from chloroform. In tetanus of the uterus, eclamptic convulsions, and maniacal labor, chloroform is to be preferred to ether, and is most useful. Profound narcosis from chloroform is seldom if ever necessary in obstetric practice, and, like this condition under ether, is attended by risk.

Germs.—Mikulicz has also found that germs are disseminated in the air from the mouth in speaking or coughing, floating on tiny bubbles of moisture. As moist germs are much more dangerous than dry ones, to reduce this evil to the minimum he limits the persons present at an "asepsis operation" to the smallest number possible, not even admitting more than six to ten students at most, and all present wear a sterilized piece of mull over their mouth, fastened to their sterilized cap; it can also inclose the beard if there is one. They soon learn to breathe through it as comfortably as a lady through her veil. Gestures take the place of words as much as possible. Flugge, the bacteriologist, considers that a surgeon with a cough or tendency to sneeze has no right to attempt an "asepsis operation."—*Southern Practitioner*, August.

Lumbricosis.—The typhoid condition which is at times noted after the administration of anthelmintics is thought from certain experiments by Tauchon (*Jour. de Méd.*, December 10, 1897) to be due to ptomains developed in the body of the ascaris by putrefaction. It has also been shown that the diseased worm, whose vitality has been decreased by certain substances, excretes a much more toxic product than in the normal state. Irregularity of the temperature curve is one of the salient characteristics of the condition.

Effects of Sulphur on the Urine.—Dr. Yvon (*La Méd. Mod.*, December 8, 1897) has found that sulphate of magnesium in doses of twenty grams increases the quantity of sulphuric acid in the urine by forty-seven per cent. Elimination is rapid and the urine is diminished. Natural sulphur in the proportionate dose of two grams and sixty centigrams is absorbed more slowly. After the subject ceases taking the drug the excreted sulphuric acid remains in excess for one or two days. The association of sulphur and sulphate of magnesium greatly increases the sulphuric acid of the urine.

A Story with a Moral, but indicating such a lack of morals as we hope cannot be frequent in England, is the following, sent by a correspondent to *The Lancet*: "SIRS: I make no comment on the following case, which I have fully investigated and every fact of which I can prove and have proved in conjunction with a colleague. A child of eleven years was suffering from a purulent vaginal discharge which was found to be gonorrhœa. On investigation it was discovered that this child had contracted it from her uncle; she had given it to her brother, aged seven years, who in turn had passed it on to his sister, aged three years. The boy of seven years had a very bad attack with phimosis and the girl of three years had it somewhat severely. On further investigation the following sidelights were discovered: The girl of eleven years felt no discomfort through connection with an adult man of about thirty years; rather the contrary. She gives a graphic and evidently truthful account of her seduction, at the age of eight years, by a boy four years her senior, since which time she has been living in frequent sexual intercourse with boys. The mother of this child three years ago gave the father syphilis and was turned out of doors, since which time she has not been back and is believed to be living the life of a common prostitute. The uncle was confronted with the girl, who accused him of having given her gonorrhœa, and on being pressed confessed in the presence of the girl's father and the husband of his own sister that it was true, and that he had done it to get rid of his own disease, having succeeded in doing so in this way on four other occasions. Meanwhile the girl's father and the other man, who were present when the remark was made, stood placid and indifferent, expressing neither indignation, disgust, nor surprise."

Diabetes Insipidus.—The syphilitic origin of diabetes is discussed in an article by Dr. Victor Bandler (*Archiv f. Dermat. und Syph.*, October, 1897). It is often a delicate question to decide whether the association of the two conditions is accidental or if the specific disease has a causative effect. A case is related which goes to prove the latter alternative.

Health Reports.—The following statistics concerning cholera, yellow fever, plague, and small-pox, have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended January 8, 1898:

CHOLERA.

		Cases.	Deaths.
India, Bombay	November 24th to December 7th.	..	8
Calcutta	November 14th to 27th.	..	28
Madras	November 20th to December 3d.	..	3

YELLOW FEVER.

Brazil, Para	December 12th to 18th.	..	15
Rio de Janeiro	November 21st to December 4th.	1	
Cuba, Cienfuegos	December 20th to 26th.	..	1
Havana	December 17th to 30th.	..	6
Matanzas	December 15th to 22d.	..	1
Sagua la Grande	December 18th to 25th.		
	Yellow fever prevailing, but impossible to obtain statistics.		

PLAGUE.

China, Hong Kong	November 7th to 20th.	2	2
India, Bombay	November 24th to December 7th.	..	253

SMALL-POX.

Brazil, Rio de Janeiro	November 21st to December 4th.	10	
China, Hong Kong	November 7th to 27th.	5	4
Cuba, Cardenas	December 19th to 25th.	..	4
Cienfuegos	December 20th to 26th.	..	3
Havana	December 17th to 30th.	..	6
Sagua la Grande	December 19th to 25th.	31	4
Gibraltar	December 6th to 12th.	1	
Italy, Messina	December 12th to 18th.	..	2
Netherlands, Amsterdam	December 12th to 18th.	1	
Rotterdam	December 12th to 25th.	2	1
Russia, Moscow	November 28th to December 11th.	2	2
Odessa	December 5th to 18th.	34	7
St. Petersburg	December 4th to 11th.	11	4
Scotland, Glasgow	December 5th to 18th.	2	
India, Madras	November 27th to December 3d.	..	1

ON SURGICAL AND OTHER HOSPITAL SERVICE. A TENTATIVE AND CRITICAL ESSAY ON HOSPITAL MANAGEMENT.[1]

By ARPAD G. GERSTER, M.D.,

SURGEON TO MOUNT SINAI HOSPITAL, CONSULTING SURGEON [illegible] HEBREW HOSPITAL, NEW YORK CITY.

Introduction.—It is proper that a fair and adequate justification should be offered by me for the introduction to this society's consideration of a subject not entirely surgical. The reasons are sufficient, I think. First and foremost of them is the fact that the New York Surgical Society is one whose membership is exclusively composed of medical men holding active service in and having a close affiliation with one or more hospitals. No body of medical men in this city is better fitted to appreciate the burden of my arguments than are you, whose intimate contact with the inner workings of our hospitals during a more or less extended period of time, in not a few instances embracing several decades of zealous and efficient work, certainly gives your opinion and judgment the stamp of highest expert authority.

The wonderful development of our branch of medicine—involving not only the command of a difficult and exacting technique, but, what is more difficult and just as essential, a thorough knowledge of pathology and of the noble art of diagnostics—would never have reached its present height without the fundamental aid the hospital has afforded to the great pioneers and discoverers by whom surgery was made what it is. What untold blessings humanity has derived from the hospital work of medical men, not only through immediate and personal service to the individual sick, but especially through fundamental acquisition of power over sickness and death through scientific discovery, need not be told here.

With the development of surgery went naturally the development of surgical hospital routine and usage, so essential to humanitarian, scientific, and economical success. Everywhere but with us this development kept pace with the increasing necessities of modern surgery. With us only is surgery hampered by forms of hospital government and polity which have become an anachronism. All the lay powers governing the concerns of the civilized nations have accorded to their medical experts that position and authority to which special knowledge and usefulness to society surely entitle them. England even has gracefully bowed to the new state of things, by the elevation of Lister to the British peerage. Only here, in America, in the most enlightened and progressive of all nations, are to medical expertness and to medical work denied consideration and deference—is denied co ordinate influence in the management of curative institutions, the chiefest work of which is performed by medical men.

My object is to expose and to brand this barbarous and disgraceful anomaly. But the argument is not to be purely one of the *pro domo* character. I intend to show that the unwise and illiberal repression and neglect of the most—in fact, the only—essential part of hospital work have been and still are damaging the interests of the patient. The enormous increase in the bulk of surgical work falling to the lot of the hospital surgeon has invested the production of what may be called the surgical apparatus—that is, the proper schooling and technical training of assistants and nurses—with the greatest practical importance, and has imposed upon the surgeon a task of great difficulty, which might be termed an art in itself. Under existing conditions high excellence in these primitive postulates of surgical success is simply a matter of happy accident, not a necessary result of the system; and, whatever shortcomings are observable in our work, they cannot be laid at the door of the visiting medical men.

Surely no extended apology is needed to bring this matter before a society exclusively composed of hospital surgeons.

Favorable First Impressions.—At the first glance, or even on closer inspection of external appearances, most of our metropolitan hospitals will, as a matter of course, make a favorable impression upon the layman. Even the more critical eye of the expert visitor will be captivated by a magnificent, often sumptuous exterior, as well as by splendid internal appointments, admirably planned for cleanliness, comfort, and convenience. The orderly, smooth, and quiet running of the complicated but well-oiled machinery of the economy of a modern large hospital can nowhere be seen better exemplified than with us. But excellent and admirable, nay, indispensable as these external characteristics are, they do not constitute the main object and purpose of the existence of a hospital.

The Medical Service is the Soul of Hospital Work.—The *punctum saliens*, the very soul of the hospital, is the curing or alleviating of disease—that is, the medical work. The more or less liberal providing of means by the community, either through taxes collected by government for the support of municipal institutions or through funds voluntarily contributed by humane benefactors, which funds are managed by boards of directors—as in the case of private corporations owning and conducting our large non-municipal hospitals—has resulted in the rise of a fine array of sumptuous, in some cases luxurious buildings, remarkably well appointed inside and outside in what appeals to the outer senses. But the very soul of these fine mechanisms, the organ around which are grouped and for the sake of which alone exist all the other members of the machinery—that is, the medical service proper, or the provisions for the immediate medical care of the patients—is in a shamefully rudimentary and neglected state. The city and nation have attained their majority, have long since ceased to be colonial and provincial. Compared with what they were fifty years ago, the dimensions of our hospitals have enormously increased; but the imperfect, make shift provisions for the medical service, adopted under the stress of penurious necessity in times of first settlement and of colonial infancy, have been retained intact to this day.

[1] Read before the New York Surgical Society, December 22, 1897.

This arraignment of existing conditions may at first appear to be too sweeping and even unjust, but I hope to show that it is based on facts which no one familiar with our hospitals can controvert. It does not imply an accusation against the zealous laymen who sacrifice time and money in managing the external mechanism of these institutions—I mean the boards of directors; nor will it detract from the unselfish and, on the whole, excellent work done, in the face of much discouragement, by the medical men connected with our hospitals. Its object is an unsparing but a just criticism of that part of the system which has outlived its utility, and, having become effete, ought to be declared dead and be cast off.

The Prevailing System of Medical Hospital Service is Effete and Must be Reformed.—First of all, the assertion must be made good that the provisions made for the medical care of our hospital patients are inadequate and unworthy of a wealthy and civilized community. This I propose to show in two separate ways: first, by a direct examination of existing methods; and second, by instituting an appropriate and fair comparison between our ways and the ways in hospital matters of the other civilized nations.

Genesis of the American Hospital.—In every community, as it emerges from the state of a village and becomes a town, there soon must arise the necessity for a provision to take care of the poor man when he is overcome by sickness. In a newly settled country thousands of instances of this interesting process of conception and birth of small institutions devoted to the care of the indigent sick can be observed. Whether the effort be private or public, the essential factors of the process are nearly identical. Small, usually inadequate provision is made for building, instalment, and maintenance, the zeal of a few sanguine enthusiasts dragging along a reluctant train of well-to-do but sluggish and more or less selfish taxpayers or patrons and protectors. As to the medical service, there is not the slightest difficulty. In a primitive community, medical services go cheap; and as the wherewithal was generously provided by the council of the struggling young town, or by a number of magnanimous donors, it is only fair and just that the medical profession should contribute to the good work its gratuitous services.

The inducements for accepting an office on the visiting staff of the new institution are many, the objections very few. True, that the work will or rather may consume much time, and that it does not bring anything to the larder. But it confers an honoring distinction, tempting to ambition, or flattering vanity, and to the seriously disposed it offers coveted and valuable opportunity for clinical observation and therapeutic effort. The services being gratuitous, the authorities feel that it would not be fair in an intensely practical society, thoroughly dominated by mercantile conceptions of life, to expect one set of men to bear the entire burden of the work. Relief is provided by the appointment of two, three, or more men to take charge of the service in alternation, each being on duty a few months only during the year. Thus the amount of work falling to the share of each of the incumbents is reduced to a minimum, and jealousy and envy are in a manner allayed. While there are a few patients only to take care of, work is scanty and much divided; on the other hand, the honors to be reaped from the arrangement are fairly and equally distributed and everybody is apt to be satisfied. In the beginning there is no segregation of patients into a medical and a surgical group. As to the house staff, not the slightest difficulty is found in filling vacancies by recent graduates from the medical schools. They get board and lodging; as a matter of course, no pay; and their terms of incumbency are short.

The marvellous development and growth of towns and cities within the last three or four decades necessarily led to the enlargement of existing hospitals and to the foundation of new ones. And thus it happened almost everywhere that, while the size and scope of these institutions have attained first-class importance, the mode of providing for the medical service has remained in its primitive state.

Governing Bodies, Municipal and Non-Municipal. Their Composition and Character.—Let us now examine what the actual working of this system is like. As to the governing bodies, they may be divided into municipal, ruled by political influences, and non-political or private corporations. The material composing the latter consists in the main of wealthy men, still active in or retired from business, with a sprinkling of clergymen and lawyers, more or less dominated by and subservient to wealth and social influence.

While it must be admitted that the character of the men who enter into the managing bodies of our private hospitals leaves nothing to be desired as to personal integrity and business capacity, the same cannot be uniformly maintained as regards the politicians to whom the conduct of our large, costly, and most important public institutions is intrusted by party.

The modern hospital is an institution in which the sick are to receive medical treatment, which is work of a scientific character of the highest order. To enable the medical men to do this work properly and efficiently, the external and material aid of a business management is necessary, the only *raison d'être* and duty of which is to provide those external conditions of shelter, food, order, cleanliness, and whatever is implied in the term of "ways and means," without which no scientific or charitable work, or, in fact, no important work of any kind, can be successfully conducted.

No Provision for a Co-ordinate Representation of Expert Knowledge in Hospital Governing Boards.—With the growth of the scope and scientific intensity of modern hospital work, the management, both business and scientific, of these institutions has become more and more complicated and difficult, and requires special knowledge and experience in those who are at the helm. Do existing conditions give any guarantee of the presence of this special knowledge and experience in those to whom the government of our hospitals is intrusted?

The answer must be, No. The fact is notorious, and need not be proven, that among the powers that direct the destinies of the nation through existing political parties fitness to fill office is looked upon as secondary to partisan efficiency. This applies, with rare exceptions, to the material from which are selected the various boards of charity. Hence we see it occur with deplorable frequency that the men managing our vast public charities neither possess capacity for business, nor have they more than a most shadowy and crude understanding of the scientific problems, the daily solution of which is the very life and heart-beat of modern hospital work. The substantial truth of this assertion is amply verified to the expert by the defective feeding and housing, by the inadequate provisions for medical and surgical instruments and apparatus, and by the generally forlorn and poorly cared for appearance of wards and patients in the overcrowded municipal hospitals.

In striking and favorable contrast with all this, we see proofs of high business efficiency in the appearance of most of those institutions which are under the care of private corporations. External solidity, internal order, cleanliness and comfort, a plentiful supply of the necessaries in the way of food, heat, lighting, of medical and surgical supplies without waste, give evidence of admirable husbanding and care. But as

soon as we enter into a close examination of the manner in which the scientific part of the work is done, here too serious defects become manifest.

Prevailing Circumstances Not Favorable to Highest Medical Efficiency.—It is only proper to state that while the vast majority of the medical men composing the medical boards of our hospitals is both capable and willing to do the best that can be done under the circumstances, the circumstances themselves are not favorable to highest efficiency. That, none the less, so much remarkably good professional work was and is being done in our hospitals, redounds to the greatest credit of the medical hospital corps, and is owing to the humane zeal and ready self-sacrifice of the American medical man.

As to individual professional achievement, we stand as high as any nation; but that all hospital work does not show uniformity and continuousness of highest excellence is not due to the lack of talent and zeal on the part of the medical men, but is the direct consequence of the crude views on and lack of appreciation of modern requirements on the part of those political and non-political managing bodies which fashion the polity of our hospitals.

In the Choice of Hospital Governors a Test of Fitness Does Not Exist.—The system now prevailing and strenuously upheld by interest, by prejudice, by self-sufficiency, by lack of knowledge of what goes on in the hospitals of the rest of the civilized world, and, let it be also said, by that wholesome inertia we call conservatism, that detests rash and unprepared change and revolution—the system is wrong, as well as are the men who consider it their duty to uphold it. Their lack of understanding of the cardinal points of medical hospital activity is due again to the faulty system which does not provide us with properly schooled and trained managers. Serving on hospital boards of management is a burdensome duty, and it is not easy to persuade men of business or leisure to assume it. Hence the range of choice is not great, and the question of special fitness is seldom if ever considered. In fact, I may state that in a conversation held on this subject with a well-known hospital manager, possessing more than the usual amount of intelligence in and understanding of matters not strictly pertaining to his occupation, great amazement was manifested when special training and technical fitness were pointed out to him as indispensable qualifications for the successful management of hospital matters. He thought that "anybody could run a hospital, it being very much like a hotel visited by medical men."

But let us see what the defects of the existing medical service are. They constitute a true "vicious circle," and it is difficult to decide where to begin.

Principles Obtaining in the Management of Public and Private Hospitals in Europe. They are Well Tested by Long Experience.—The care for and responsible direction of a large hospital service is an office of the highest dignity, and is recognized as such in all civilized nations except ours, by granting to the medical men holding it both security of position and ample remuneration, together with that influence in the responsible but independent management of the service as to appointment of assistants, ward discipline, the initiation of necessary changes and improvements, that is inseparable from thorough responsibility. No novice ought ever to be intrusted with such a position, and candidates ought to be men of professional excellence and efficiency universally acknowledged by profession and laity. To the layman, "professional excellence" very often signifies a large or lucrative private practice, which does not by any means insure success in hospital work. In a certain sense it impedes it, as it demands indispensable time and close attention, both needed for every kind of good work.

Long service as an assistant, literary and scientific work, and independent service in a smaller hospital, are the legitimate stepping-stones to such a position, and though personal favor and individual attractiveness of manner and disposition ought to receive decent attention, they ought not to overshadow those qualifications which are acquired only through long and faithful service.

Present Manner of Appointment of Visiting Men Improper and Humiliating to Medical Men. Undignified Scramble for Vacant Positions. A Call Should be Extended to the Preferred Candidate.—Positions of this character and weight cannot and ought not to be filled by the undignified scramble witnessed here whenever a hospital appointment becomes vacant. Men of acknowledged ability and position ought not to be expected to hand in an application to the appointing powers, humiliating to the candidate and unworthy of an enlightened body of managers; but a wise choice among available men of the proper weight ought to be made concurrently by the medical and lay boards of the institution in question, a call being extended to the first choice, as is done when a clergyman is to be appointed. Preferment of this kind is a real honor, and can be accepted or declined. In the latter case, a second or third choice might be available.

The appointment made, the solidarity of the new officer with the institution and its welfare is absolute. He has permanent and sole charge of a large and attractive service, and by dint of an adequate salary is, in proportion to its size, more or less independent of the necessity for earning his bread outside of the institution. His duty is first and foremost to the service of the hospital, and includes the daily and minute personal supervision of the treatment of every patient intrusted to his care. Permanency of service and the obligation entailed by financial remuneration create a responsibility and strictness of official obligation entirely different from what can be fairly and reasonably expected when services are gratuitous.

Scientific work and literary activity naturally thrive in such an atmosphere, and will inevitably redound to the direct benefit of each individual patient treated and, by scientific discovery and progress in methods of practice, to the gain of suffering mankind in general.

The training of assistants, who also ought to be attracted by moderate pay and longer tenure of office, will be much more satisfactory than at present, and will provide a corps of candidates thoroughly competent to advance to and creditably fill higher positions. Absolute regularity of hours for visits and for operations, and an orderly routine of daily work, secure order and regularity down to the duties of the last scullion, and insure the comfort and welfare of patients, by eliminating haste, disorder, hollow excuses for neglect of duty on the part of nurses and house staff, creating an air of promptness and serene precision.

An arrangement like this, not imaginary, but yielding excellent results on the continent of Europe and to a respectable measure in Great Britain, has other attractive sides of an economical character. Waste of food, drink, surgical and medical material, is readily noticed and checked by the chief of the service, who can be and is made responsible for it.

Description of Present State of Hospital Medical Services. Parcellation. Irregular Visits of Attending Men. The Bulk of the Work Done by an Inexperienced House Staff.—What do we see instead of all this? As the concentrated and undivided attention of the visiting man, who must earn his bread in outside practice, cannot be given to his hospital appointment during the entire year, two, four, or even

five and six men are invested with the care of, for instance, sixty or eighty patients—the usual size of a hospital department. Either they serve in alternation, or two or more serve simultaneously, dividing the number of beds among them. Each visiting man comes when he can or when it pleases him, rarely twice in succession at the same hour: a systematic and detailed visit of each patient daily is out of the question, and is not only unnecessary but even irksome, especially to surgical patients who are in any way attended to and dressed at morning rounds by the house surgeon.

As a rule, only patients who, in the opinion of the house surgeon—*sit venia verbo*—are not doing well are presented to the visiting man, and the inclination to get through with as little bother as possible is natural, and the direct consequence of the fact that the real and detailed daily and hourly treatment is entirely in the hands of an enthusiastic but inexperienced, often indiscreet, and occasionally vicious and incompetent house physician or surgeon. I shall presently recur to the house staff.

With the increase of large reputations and large practices, we have finally arrived at a state of affairs wherein the visiting man of a hospital has often virtually ceased to be the man "in ordinary" that he ought to be—and that decent hospital management of this day ought to provide and owes to the patients it undertakes to take care of—and has instead become practically a consultant to the house staff. The tendency is natural, and the blame for it does not rest with the visiting staff so much as with the vicious system. That the tendency is real is manifested by the rule found in the bylaws of almost all of the various city hospitals, where it is expressly ordered that the visiting men on duty must see personally every patient in their service at least twice a week.

Demoralization of the House Staff. System Great Peril to Patients. Confusion of Ideas Caused in the House Staff by Frequent Changes of their Medical Superiors. Operating Mania.—With the multiplicity of medical officers simultaneously on duty; the irregularity of their visits: in the surgical branches with the weight of the work unduly thrown into the operating-room, a pernicious state of demoralization of the house staff is indissolubly connected. This is still more intensified by the circumstance that the unformed, crude notions of the young medicos are continually shaken and upset by real or mostly seeming contradiction in the principles enunciated by the various visiting men who serve at the same time or in quick and merry succession. Hardly has A broken them in to the observance of a modicum of surgical cleanliness in manipulations at the bedside or in the operating-room, when B enters, and, presto! the whole structure of aseptics is declared to be rubbish, and sparadrap, balsam Peru, and the smells of suppuration and sloughing pervade the air.

So it happens that, instead of honoring and respecting their leaders, they criticise and ridicule them, throw overboard much that is important together with rubbish, do only what they in their raw infantility consider to be proper, neglect at the bedside the painstaking observation and recording of the inconspicuous but important features of disease, strive after showy operations in the surgical service, without learning to make a decent diagnosis or knowing or caring for decent, painstaking after-treatment. So it happens that the medical histories, if at all in existence, present a mixture of truth and pleasing fiction; that abuses of the grossest kind creep in and have to be suppressed by draconic enactments. For instance, I may mention what recently happened in a large metropolitan hospital, where the house staff, on their own hook and against the wish of the visiting physician, subjected systematically, and of course secretly, patients suffering from typhoid fever to most heroic treatment by cold-water plunge baths and cold packs.

Competitive Examinations of Candidates for House Staff No Test of Fitness.—If only the welfare of the patient is to be considered, the present cheap and wretched method of providing hospital assistants ought directly to be abolished. They are the very men to whose immediate care is intrusted the patient, and who, with rare exceptions, are not fit to carry such responsiblity. Without practical training, they secure their hospital appointment by means of a necessarily theoretical examination of very questionable value in determining executive ability, discretion, and soundness of character. Honor men, and those who pass written and oral examinations with flying colors, often turn out to be perfectly worthless in service; and no wonder, since a course of intense cramming of a receptive memory offers not the least security against practical incompetence.

As far as the house staff is concerned, the zealous and earnest hospital man is in the perennial position of maintaining a sort of medical kindergarten, where A B C is taught year in and year out. By the time that the better men on the house staff become undoubtedly useful, and are ready and fit to be of real assistance, they pack their trunks and depart.

Unwarrantably Great Scope Given to House Staff in Hospitals. A Systematic Activity of House Staff Impossible under the Present System.—Much more glaring than in the hospitals managed by private corporations are the abuses in the institutions governed by the boards of charity; abuses dependent upon the unpaid, subdivided, cut up, unregulated, and generally makeshift character of the visiting medical service, and also dependent upon the logical outgrowth of such a crude system of service—that is, the inevitable circumstance that too much scope is given to an unavoidably immature and to a great extent irresponsible house staff. But this is the only kind of a house staff that can be had under existing beggarly provisions.

Assuming, on the other hand, that the house staff were thoroughly trained, competent, and mature, even then the lack of system and order in the medical service, as far as the visiting staff is concerned, would hamper efficiency to a fatal degree. To any one familiar with the ways of our city hospitals, the fact is well known that no rounds, no operation, in fact hardly any work requiring time and care, is ever allowed to go on uninterruptedly. The visiting men, with few laudable exceptions, maintain no fixed days or hours for their visits or even for their operations; hence the house staff is kept in a state of unceasing *qui vive*, extremely fatal to good, conscientious work on the part of those who are willing, and offering an inexhaustible source of real and imaginary excuses for neglect of duty on the part of the shirkers.

The Present Beggarly System Inexcusable in the Hospitals of One of the Richest Cities of Christendom. A Well-Organized and Decently Paid Medical Service a Necessity.—There is not the slightest excuse for the maintenance of this uncivilized state of affairs in the public hospitals of one of the largest and richest cities of Christendom, and it is time that the disgrace of the thing should be unsparingly laid bare. It is the duty of medical men to hammer away at the existing condition of things, and to insist that the community has a moral obligation to take care decently of its indigent sick, as it is fully able to do, in a manner required by modern exigencies. Every large town and city of Europe has its admirably equipped hospital, served by paid medical men from the top to the bottom of the ladder, and there is no valid excuse from the plain duty of New York City to provide its hospitals with a well-organized and well-paid, there-

fore efficient medical service. The present beggarly makeshift is an unjust burden upon the profession, and cannot yield more even at its best than a surrogatum for the real thing.

The Attending Staffs.—The modern and civilized postulates for a decent care of hospital patients require:

First, daily personal attendance of one competent and permanent medical chief to each hospital department of about one hundred to one hundred and fifty beds, which should take place at regular hours, preferably in the morning. This would at once result in a natural systematization and regularity of all the subordinate factors, such as are the assistants, nursing, kitchen, drugstore, etc., and would be followed by the greatest benefit to the patient. The chief of each municipal hospital service should receive adequate compensation, should be irremovable up to a certain age during good behavior, and should be permitted to practise in the afternoons. The chiefs of the various hospital services ought to have an official and effective representation in the board of charity in the person of a medical man. The wardens of all hospitals should be medical men possessing requisite and proven business capacity.

Staff of Assistants.—Secondly, on the house staff the term of service should not be limited, and, to encourage long service, the assistants in the higher grades should receive a modest salary and board and lodging. To enable young graduates to gain hospital experience, a limited number of dressers or volunteers should be admitted to each service without pay, who should have all the privileges now enjoyed by juniors, assuming, on the other hand, all the duties and obligations of such for one year. Vacancies in the corps of dressers or volunteers should be filled by examinations held by each chief for his own department—the permanent assistants to be selected from among the volunteers or dressers, whose practical capacity and value could be excellently tested during their service embracing one year.

These are the changes, radical but feasible, that ought to be aimed at in our public hospitals. Their acceptance would work marvels, and would promptly effect the transformation of a department long mismanaged through lack of competence into one that would be the just pride of every humane citizen of New York.

Private Corporations. Timber of Their Boards of Management. Excellencies and Defects. Suspicious Jealousy of Laymen toward the Expert.—As regards the management of the hospitals owned by private corporations, this can be said: that while most of the timber of which the typical board of directors is composed is just as unqualified in matters of expert training and knowledge as the political *personnel* of which our charity commissions usually consists, the former rarely if ever contains names not of unquestioned standing and integrity, which cannot be said to be uniformly the case with political office holders.

This advantage on the part of the hospital boards based on private charity is somewhat counterbalanced by the fact that, with few exceptions, they constitute close corporations, irresponsible to the members of their respective institutions, hence inclined to be narrow in the conception of their rights and duties, and not rarely inconsiderate and despotic in the exercise of their prerogatives. Not overtolerant of criticism, they too often exhibit the suspicious jealousy of the layman toward experts of all kinds. To this attitude, so often exhibited by lay directors toward their medical co-workers, is attributable the barbarous anomaly that, with the exception of two, none of our private hospitals admit any medical man to their boards of directors. The honorable exceptions are St. Luke's with one member and the German Hospital with three medical members in the board of trustees.

Humiliating Conditions under which Medical Appointments are Made.—To this narrow-minded, thoroughly petty, and illiberal spirit is due the fact that the men who, by professional training, expert knowledge, and skill, are most competent to mould the understanding of unskilled laymen as to hospital matters, are excluded from any but an apologetically advisory influence upon the polity of those institutions, the essential work of which is performed by them at the expense of much labor of mind and body. Whoever wishes to become a member of the visiting staff to a hospital in New York must send in a humble application, like a butler seeking a desirable position. Appointments of medical men are either made annually—just like underservants—or are held "at the pleasure of the board;" in short, the tenure of a hospital position can be made and unmade without due process or even a decent explanation—a state of affairs equally humiliating to those who exact and to those who submit. And yet, in spite of all this, the very pulse beat of these hospitals is furnished, not by the overbearing managers, but by the medical men. Likewise, the good or bad name of a hospital depends not upon the managers, but upon the work of the medical men.

Representation of Expert Knowledge in the Management ought to be Obligatory.—Not only fairness, but the plain interest of the patients committing themselves to the care of a hospital—in short, the welfare of the institution, demand that expert knowledge be represented in the lay, hence in technical matters more or less uninformed, boards of management.

As to the appointment and tenure of the visiting staff of private hospitals, the same principles ought to prevail which were proposed for our municipal institutions. Abroad, no private charity of this kind can receive the sanction of government without the proof of ample and secure provision for maintenance, which of course includes the salaries of all medical officers. Here, in some well-known instances, with the reckless expenditure of money upon magnificent buildings, far in advance of existing necessities, no available funds are left for even that maintenance in which the work of the medical men remains unpaid. Hence it would be hopeless at the present time to clamor for medical salaries in private hospitals, however just and politic such a thing might be. But much improvement is possible even in the medical service of these impecunious hospitals. Let the superintendent be a medical man; let each department have a single, permanent head, irremovable during good behavior, or appointed for a term of, say, ten years, aided by one or two assistant or adjunct visiting men. Roosevelt has taken the initiative in this direction, and her liberal and enlightened management has every reason to be satisfied with this step in the right direction. Mt. Sinai bids fair to follow suit, and as a proper appreciation of medical matters and of the interest of the patients penetrates the fog surrounding some of our managing boards, so the defects of the present many-headed and interrupted services will disappear. No crops of wheat can be raised on the turnpike road.

Methods of Agitation to be Pursued to Bring about Needed Reform. United Action of the Profession Chimerical on Account of Severe Competition. Success must Come through Conversion of those who Furnish the Money. Now, as to the possibility and means of bringing up hospital activity in this city to the modern level of efficiency, to the standard long accepted by all other civilized metropolitan communities, and the only one worthy of New York, I have to say this: the remedy so often urged by medical men as a panacea, namely

a firmly solidary and united profession, is chimerical for many reasons. First of all, entrance to the profession is still too easy, hence competition extremely acute. With the inrush of promiscuous elements from the various trades, elements lacking even vestiges of a liberal education, the transplantation of the mental and moral attitude of the trader into medicine is only too obvious. Add to this the pangs of domestic need, and then, with no *esprit de corps* and hunger gnawing at the entrails, self-respect and respect for one's profession will easily be thrown aside for momentary or for permanent gain.

That prominent professional and social standing, fame, and a lucrative practice offer no security against lapses from self-respect and decency, is only too well known. It is also natural, when the medical man, instead of excelling his lay surroundings by "high thinking and plain living," by that superiority and distinction which come from a wider and deeper knowledge, enters into a competition of worldly pomp and luxury with a rich and thoroughly worldly clientèle, that pressure or blandishment of a certain kind will produce the same effect upon him as poverty and need will call forth in the struggling beginner. With increased expenditure, the necessities for maintaining social and professional prestige will compel even the most successful practitioner to strive for and to cling to a hospital position at all hazards. Hence there will always be small men and big men ready to take and to hold a hospital position under even more humiliating conditions than those now prevailing. In short, it is absurd to talk of a firmly united profession.

We can accomplish something only by appealing to the enlightened and progressive laity. But we medical men, especially those whose opinions command respect, must come to a full realization of the fact that a thoroughly self-respecting and genuine way of bestowing medical charity under a modest, unpretentious roof is far better than the present state of beggarly pomp and hollow magnificence of external splendor, with the core and *punctum saliens*, the only *raison d'être* of hospitals—the medical care of the poor sick—in a shabbily neglected and unworthily rudimentary state of development. And the system of medical service of our hospitals must remain incomplete and rudimentary as long as it is extracted, as at present, from the Cinderella of all professions by an unfair bargain.

Agitation by incessant appeals to the enlightened taxpayer will undoubtedly result in a rational organization of the medical service of the public hospitals, though much time and labor must be expended to secure to patient and medical man their due. Public charity is not only charity in the scriptural sense, but is a function of self-defence which modern society owes to itself, and which in all civilized nations except ours receives the highest consideration of State and municipality in every way and respect.

As to the reform of the medical service in our private hospitals, here again changes must be brought about, not by "strikes" and warlike measures of doubtful taste and undoubted worthlessness, but by tireless and patient propaganda among that part of the laity upon whose financial support these institutions depend. Let the opinions here enunciated come to the most self-sufficient and impregnable board of managers, supported by a large endowment, bequest, or donation, and we shall see that minds habitually inaccessible to "mere reason" will lend ear respectfully, and will adopt with alacrity what, unsupported by such an argument, appeared to be impossible. Our work must be among those laymen who, by natural gift, education, and travel, are above the level of the ordinary type of the successful business man. If every one of us will faithfully and, let it be said, also skilfully perform this missionary labor in his own circle of friends, the desired result must come sooner or later.

With competent and zealous medical men wisely repressing the natural inclination of laymen toward the cultivation of the showy, external part of charitable work, luxurious palaces, half-filled with patients, who are indifferently cared for by an antiquated and effete system of medical service, will not be erected far in advance of existing demand; huge deficits will not yawn in every annual report upon the patrons and supporters of so many hospitals: and mutual concession and respect among the lay and professional laborers in this field of charity will certainly result in a better care of the patient, and, on the part of the medical men, in the consciousness of work well done, because properly acknowledged and rewarded.

Conclusion.—To sum up we may say:

1. That the present manner in which provision is made for the medical work in municipal and private hospitals is crude, inefficient, and unfair, both to patient and medical man.

2. That all municipal hospitals ought to be provided with permanent medical officers, whose adequate remuneration should be defrayed by taxation: that superintendents and wardens should always be medical graduates of tested business capacity.

3. That, by introducing a permanent and continuous service, each hospital department of about one hundred or one hundred and fifty beds should be directed by one responsible chief, having safe tenure during good behavior, aided by a corps of paid assistants.

4. Private hospitals with limited means should not erect costly and vast buildings maintained with much difficulty, but should rather spend their means in providing a paid corps of permanent medical officers. Even a modest salary would insure daily and zealous attendance on the part of the visiting men, whose number would be reduced at the ratio of one chief to one hundred or one hundred and fifty beds. In the mean time, while payment for medical work, to be provided for by endowments or otherwise, is not feasible, important and valuable improvement is possible: first, through unification, continuity, and permanency of the services: and second, through encouragement of a longer service on the part of the members of the house staff by the payment of modest salaries.

5. The responsible heads of the various departments should have adequate, compulsory representation in the governing body of each hospital.

Is Dysentery a Cause of Stricture of the Rectum?—Although it is frequently stated that dysentery is a common cause of stricture of the rectum, I have never seen a case of sufficient worth to convince me of the truth of the statement, or indeed that it was a cause at all. I have many times seen patients who gave a history of having had dysentery and who were treated for a long time for that affection, but a close scrutiny of the case revealed the fact that the so-called dysentery was caused by an already existing stricture and ulceration, the rule here being reversed—that dysentery was the result and not the cause. If dysentery really be a cause of stricture of the rectum, how very often one would expect to meet with it in practice, considering the great number of people who have dysentery, especially in warmer climates. Again, practitioners of medicine know that ulceration proper very seldom exists in the rectum during or after attacks of dysentery. I do not deny, but my experience has taught me that ulceration of the rectum is not caused by repeated attacks of dysentery or diarrhœa. I am sure at least that these causes are infrequent.—Mathews.

THE MANAGEMENT OF PATIENTS BEFORE AND AFTER LAPAROTOMY.[1]

By FREDERICK HOLME WIGGIN, M.D.

VISITING GYNÆCOLOGIST TO THE NEW YORK CITY HOSPITAL; [illegible] ST. ELIZABETH'S HOSPITAL; THIRD VICE-PRESIDENT, AMERICAN MEDICAL ASSOCIATION, ETC.

In the early days of the decade now drawing to a close, it was generally considered to be a fact that operations within the abdominal cavity could be performed, with a reasonable degree of safety to the patient, only when undertaken in expensively constructed special rooms attached to either public or private hospitals. But as time has gone on and our knowledge of bacteriology has increased, antiseptic surgery has been gradually replaced by aseptic work, and we have found, especially those of us whose fortune it has been to perform operations of the class under consideration in ordinary houses, that, although the personal effort and responsibility are increased, abdominal operations can be performed with as little if not less danger to life in a properly prepared room in the patient's dwelling as in the best-equipped modern hospital. This, coupled with the fact that abdominal wounds are more frequently closed without drainage, and therefore allowed to heal under one dressing, than was formerly the case, seems to make it evident that the time is not far distant, if indeed it has not already arrived, when patients suffering from abdominal disorders will ordinarily prefer to be operated upon in their own homes, rather than to go among strangers in a strange land at this critical time. Hence it will come to pass that the general practitioner in the near future will more often have an important part to play in the management of patients, both before and after the performance of laparotomy, than has hitherto been customary. On this account chiefly the discussion of this important subject has seemed timely, for it is the writer's belief, founded on a considerable experience, that the patient's welfare depends not only upon the technique of the operation itself being properly carried out, but also upon the successful management of many so-called minor and therefore neglected details, both before and after the operation. Years ago the writer, then under the pupilage of that great surgeon, Prof. James R. Wood, learned that the most successful surgeon was he who could best carry out not only the major but the minor details of his work; and this must be his excuse, if one is needed, for the minuteness with which the minor points of routine work are about to be gone into.

Preparation of the Patient.—When the condition for which the operation is to be undertaken is chronic, and all the time desired can be had for the preparation of the patient for the ordeal which he is to undergo, much can be done which will not only diminish the risk about to be incurred by him, but which will ultimately hasten convalescence. In such a case it is for the patient's welfare that the hospital where the operation is to be performed should be reached, or the trained nurse employed if the patient is to remain at home, at least one week prior to the date fixed upon for the operation. This allows the individual to become accustomed to the attendants or the environment, which is of undoubted importance, as it tends to lessen the dread and nervous tension, both of which are great in such a crisis, even under the best of circumstances. During this week the sufferer should be encouraged to spend the greater part of the time in bed, for the purpose of getting thoroughly rested; as patients too often come under operation physically exhausted. During this period massage may be employed to advantage in lieu of physical exertion, as it improves the circulation and promotes digestion and the general bodily welfare. As far as is compatible with a healthy mental condition, visitors and friends should be excluded. A daily record of the patient's bodily temperature, pulse, and respirations should be kept. An examination of the heart and lungs and a final analysis of the urine should be made at this time. As it is of great importance that the intestinal canal be thoroughly collapsed at the time of operation, careful attention should be paid to unloading and emptying the bowels, as well as to getting the digestive organs in good working order. This is best accomplished by giving early in the week several small doses of calomel and soda, daily for three days. These are to be followed each morning by a saline, and this in turn, on each of three succeeding mornings, by a large enema, unless contraindicated (three to four quarts of saline solution—one drachm to the quart). The rectum should be finally washed out with a pint of the same solution, six hours before the performance of the operation. The large enema just alluded to is best given with the patient lying on the left side, a fountain syringe being used for the purpose, the reservoir of which should not be elevated more than three feet above the patient's body. A bulb syringe should not be used for this purpose; for, in the first place, it injects the fluid irregularly and with too much force, and consequently only a small quantity can be employed: in the second place, it is apt, if carelessly used, to permit the entrance of air into the bowel. An instance of this sort came under the writer's observation some years since. A nurse, having been directed to give a patient an enema, undertook to force fluid contained in a pitcher into the gut by means of a bulb syringe. She worked away vigorously for a time, directing all her attention to the patient, who complained bitterly; but she failed to notice until it was too late that the distal extremity of the tube had escaped from the fluid, and the patient's abdomen was greatly overdistended. The family physician was hastily summoned, and with some difficulty relieved the patient from a very severe attack of wind colic.

The fluid for the enema should have a temperature of 100° F., and should be introduced into the canal slowly, being frequently intermitted as the patient complains of a feeling of distention or of intestinal colic. Both of these sensations pass off with the cessation of the flow, and by perseverance in this way three or four quarts of saline solution can usually be introduced into the colon in the course of half an hour, with but slight discomfort to the patient. The patient should be encouraged to retain the fluid for another fifteen minutes before it is allowed to escape. The administration of these enemata should be supervised by the physician, as the nurse seldom knows how to accomplish the introduction of the desired quantity of fluid into the intestinal tract, or, if she has the knowledge and experience, she has not sufficient authority over the patient to effect the desired result. The writer has often been told by nurses intrusted with this duty that they have given the enema of four quarts, not as ordered, but in divided doses, thinking probably that, as "twice two equals four," they had performed their duty in a satisfactory manner. It is this misunderstanding that so often causes the patient's bowels to act on the operating-table, not only to the great discomfort of the surgeon and his assistants, but frequently, when the operation is about the vagina, endangering the patient's life.

The course indicated for cleaning and emptying the intestinal tract has proved in the writer's experience to be a much more satisfactory one than that generally employed—*i.e.*, the administration of a single large dose of calomel the evening previous to the day set for the operation, and followed in the morning by a saline

[1] Read before the Hartford Medical Society and the New York Medico-Surgical Society at their January, 1898, meetings.

and a small enema. The latter method usually fails properly to empty the colon, but succeeds, as has been already said, in causing several movements after the patient has been placed under the anæsthetic and on the operating-table.

The patient's diet during this week of preparation should be of an easily digestible nature, and he should be encouraged to partake freely of liquids, for the purpose of restoring the normal quantity of fluids in the body. If needed, cardiac stimulants should also be given. Hot baths (110° F.) of ten minutes' duration should be given daily, not only for cleansing purposes, but to promote the secretions of the skin and kidneys. Special attention should be paid to the navel and pubic region, which should, if practicable, be shaved on the day previous to that fixed upon for the operation; otherwise it must be done after the patient has been placed under the anæsthetic. If the individual is a female, the time of the operation should be, when possible, arranged for a few days following the cessation of the menstrual flow, and a vaginal douche should be given, consisting of boric acid, and followed by one of formalin (one-half per cent.) or of bichloride (1 to 4,000). It is well during these days preceding the operation to give the patient a mild hypnotic every other night. The writer has found a combination of sulfonal and chloralamid to answer the purpose. This hypnotic should be given always on the last night of the period under consideration.

The patient's skin covering the abdomen should be prepared for the surgeon by thoroughly cleansing it, applying a soap poultice for two hours over the site of the proposed incision, and then replacing it by a compress moistened in weak bichloride solution. This compress is allowed to remain until the patient is placed on the operating-table. These preparations can be made the evening before, if the operation is to be performed at an early hour in the morning; or in the morning, if an afternoon hour has been decided upon.

It is wise to fix upon as early an hour of the day as practicable, as the patient in this case has less time in which to become exhausted from want of food, or restless or nervous from the dread of what is to come. It is of great importance that once the hour has been determined there should be no postponement, as the writer has seen patients almost collapse under the extra nervous strain entailed by half an hour's delay.

If the operation is to be performed at an early morning hour (*i.e.*, 8 A.M.), the patient should be given a peptonized milk punch at eleven o'clock the previous evening, and if he awakens at 5 or 6 A.M. one ounce of liquid peptonoids may be given, but nothing more. It has been the writer's experience that a small amount (one ounce) of stimulating and concentrated food, administered about two hours prior to the taking of the anæsthetic, diminishes the liability to heart failure, and also lessens the nausea and vomiting which frequently follow the return to consciousness. If an afternoon hour has been decided upon, another peptonized milk punch may be given the patient when he awakes, and one ounce of liquid beef peptonoids at 11 A.M. If the case is of an acute character and an immediate operation is demanded, little more can be done than to cleanse the skin in the manner already described, and douching out the vagina if the patient is a female. A stimulant should be administered if the pulse is feeble or if the patient is suffering from collapse due to intestinal perforation. In this condition, if the patient does not respond to the stimulants, the operation should not be performed, as it will prove of no avail. If, on the other hand, the patient rallies, the operation should be done with as little delay as is practicable; but even in these cases it should not be forgotten, as Dr. Abbe has pointed out, that if we would have our work come to a successful issue we must have good light, good assistants, and proper facilities for intra-abdominal irrigation.

If the operation is to be performed in a private residence, a room with a north light should be preferably selected. Its furniture should be removed at least twenty-four hours before the room is to be used. After it has been thoroughly cleansed, the windows should be left wide open for two or three hours, then closed, and the woodwork wiped off with bichloride solution, 1 to 1,000. The floor should be liberally sprinkled with a similar solution. A table, twenty inches wide by thirty inches high, and varying in length according to circumstances, will be needed, as well as several smaller tables or stands, a few wooden-bottomed chairs, several large pitchers, four or five basins, several meat platters, and a receptacle (a fish kettle) for sterilizing the surgeon's instruments. All these articles should be cleaned and washed off with bichloride solution before being placed in the operating-room. The room should be closed after all the articles have been placed in it, and should remain so until needed. A dozen towels, sterilized by boiling or by steaming in a sterilizer, and several gallons of cold and hot water, sterilized by boiling, complete the arrangements to be made before the arrival of the surgeon, who usually provides instruments, ligatures, suture materials, and dressings. For emergency operations it is best to make no attempt to clean the room, but the floor should be covered with a sheet wet with bichloride solution. This avoids vitiating the air of the room with dust—a thing greatly dreaded by the surgeon.

The patient should be so clad for the operation as to reduce to a minimum the bodily exposure. The clothing should consist of a warm undershirt, drawers, and stockings—the last-named often being made in one piece.

The anæsthetic should be administered to the patient before he is brought into the operating-room. If the anæsthetic to be employed is ether, it is advisable to administer hypodermically one-eighth of a grain of morphine and one-one-hundredth of a grain of atropine, half an hour before the induction of the narcosis, as this tends to diminish bronchial secretion and materially lessens the amount of ether to be given. If, for the administration of the ether, a closed inhaler is used, of the Clover type, and the gauze contents are saturated with the fluid at the start, and the mouth-piece is rapidly brought down over the patient's nose and chin, so as to exclude the air, the anæsthetic state will be quickly induced, and there will seldom be a stage of excitement. It is a fact that patients can be rendered unconscious and kept in this condition for an hour with only four ounces of ether, and for the second hour with only two additional ounces.

After the patient has been placed under the influence of the anæsthetic agent, and put upon the operating-table, on which sterilized blankets have been placed in such a manner as to admit of their being folded over the patient's chest and lower limbs, leaving only the abdomen exposed, the bichloride compress previously alluded to is removed, and the skin is finally scrubbed with hot water and tincture of green soap. The pubic and umbilical regions should receive special attention. This scrubbing is to be followed by irrigation with sterilized water, ether, and alcohol. If the patient is a female, it should be the rule to cleanse the vagina in the same manner, but, instead of scrubbing the tissues with a brush, it is better to use a piece of gauze, held in the jaws of a sponge-holder, as the brush tends to excoriate the tissues and thereby increases the danger of septic infection.

While the technique of abdominal operations is not within the scope of this paper, the writer asks leave to say that for a long time past he has been in the

habit of entering the abdominal cavity by means of an incision through either the left or right rectus muscle, as the case required, the muscle being simply split, and not divided. This incision heals readily, and there appears to be little danger of ventral hernia, provided the edges of the fascia are approximated. The appendix can be readily reached and removed through the incision over the right rectus muscle. Not long since the writer removed the greater portion of a long and adherent appendix through an incision made over the left rectus muscle for the purpose of removing the left ovary. Of course, this last incision is not recommended for the removal of the appendix.

Before closing the wound in the abdominal wall, it has been the writer's custom in most instances, notably in those cases in which the formation of adhesions between the viscera was undesirable, to leave behind in the general cavity a considerable quantity of so-called normal salt solution (one-half drachm to the pint), at a temperature of 110° F., after irrigating the cavity freely with the same solution. This not only, in his opinion, tends to prevent the formation of intestinal adhesions, but also serves to stimulate the patient, who generally leaves the table in good condition and with a warm, moist skin. The edges of the wound are approximated by means of a single row of silkworm-gut sutures, which pass through all the different layers of tissues. The writer has gradually learned that these deep sutures should be placed at least one inch apart, and loosely tied, so as to allow for the swelling of the parts, which is considerable and varies in amount with the thickness of the wall. The interference with the circulation by means of these deep sutures, when placed too closely together and tied so as to approximate the edges of the skin accurately, is, he believes, a more frequent cause of stitch abscess than is infection. After the deep sutures have been tied as indicated, the edges of the skin should be accurately adjusted by means of a buried running suture of silkworm gut or by a continuous suture of catgut.

While the operation is progressing, the anæsthetizer, who should be an experienced physician, should watch the patient constantly and pay no attention to the operator. As soon as the reflexes have disappeared, he should raise the inhaler from the patient's face, to replace it as soon as they return. In this way the patient inhales the minimum amount of ether and carbonic-acid gas. As soon as the pulse increases twenty or thirty beats a minute, a stimulating hypodermic injection of strychnine should be administered and repeated as needed from time to time, until one-twelfth of a grain has been given. To this may be added one-one-hundredth of a grain of nitroglycerin, every fifteen minutes. If, in spite of these stimulating injections, the pulse exceeds 150 beats a minute, it is well to open either the right or left median cephalic vein and introduce into the circulation from one to two pints of saline solution at 100 F. This solution should be made ready in advance. For giving such an injection a simple apparatus, consisting of a rubber tube with a funnel at one end and a blunt hollow needle at the other, is all that is requisite.

After-Treatment.—The operation having been completed, the wound dusted over with acetanilid powder, and the usual dressings applied, the patient should be returned to his bed, being placed directly within the folds of a blanket and surrounded, if necessary, with hot-water bags or bottles. Care should be taken lest they be overheated and so blister the still partially unconscious patient. This warning is given because it is not at all uncommon, when the matter is left entirely to the nurse, to have the patient receive one or more severe burns from this cause. When a quantity of hot saline solution, already alluded to, is allowed to remain in the abdominal cavity, the patient generally leaves the operating-table in good condition, and with a warm, moist skin. If the patient's pulse is weak and rapid it is wise to raise the foot of the bed somewhat, and soon after consciousness has been fully regained to administer one-eighth of a grain of morphine and one-one-hundredth of a grain of atropine to quiet the patient and combat shock. There is, however, usually very little shock unless there has been much blood lost during the operation. After this one dose the use of morphine should be discontinued, as it deranges the digestive system and obscures the various symptoms. It is not necessary to keep the patient in one position during the first three or four days. In a recent hospital case this was well demonstrated by the fact that, although the patient fell out of bed the night following the operation, convalescence was smooth and uneventful.

During the first twelve or eighteen hours following the operation the patient should not be allowed anything by mouth except a little warm water from time to time. If ether has been administered intelligently in small quantities and in the manner previously described, there will generally be little or no vomiting or nausea, and when either of these does occur it can be overcome by the external application of chloroform to the epigastrium. If the demand for fluids is urgent, which is seldom the case when the saline solution is left in the general cavity, it is due to gastric irritation, and can usually be successfully combated by two or three large doses of subnitrate of bismuth. The patient should during these early hours of convalescence be stimulated and nourished, if necessary, by means of enemata, unless the operation has involved the breaking up of extensive and firm adhesions in the pelvic cavity, in which case a weak place in the bowel may be ruptured and the enema and fæcal contents of the lower bowel be forced into the general peritoneal cavity. This accident has occurred twice in the past two years in the writer's practice. With the passing of these first twelve or eighteen hours, if the patient is not suffering from nausea or vomiting, and the pulse rate is much the same as before the operation, a drachm of liquid beef peptonoids or of some other similar preparation may be given, and repeated if well borne, every twenty minutes until four doses have been taken, when after an interval of two hours a small quantity of equal parts of milk and lime water or of peptonized milk may be given from time to time, until four ounces has been taken. After this there should be an interval of two hours and then half an ounce of liquid peptonoids may be administered. After another interval of two hours four ounces of peptonized milk may again be given. The quantity of milk should be gradually increased and the interval lengthened, until the patient takes eight ounces or its equivalent every three hours, but once during the twenty-four hours the interval should be lengthened to six hours. The general tendency is to give too small quantities of nourishment at too frequent intervals, which fatigues the stomach and is apt to cause irritability of this organ, and engender a disgust for food. During the interval if the patient desires more liquid, egg albumen and water (the whites of three eggs to a pint of water, to which a little salt has been added) may be allowed him frequently.

During the first forty-eight hours following the operation, if the patient is disturbed by reason of intestinal gas, great relief is often afforded by the introduction through the sphincter ani of a short rectal tube, or even the nozzle of a fountain syringe.

Some time since, the writer performed a laparotomy upon an out-of-town patient, and left her the following morning in the care of her physician, whose experience in abdominal cases after operation was limited. A few hours later, the woman began to complain of severe abdominal pains and distention. The medical man

was summoned, and after examination diagnosticated the condition as symptomatic of peritonitis. Fortunately, instead of giving morphine, he called in a brother physician who had had some experience in the care of such cases. After examining the patient the latter inserted the rectal tube of a fountain syringe into the bowel, and was rewarded by a rush of escaping gas. The abdominal distention and pain quickly disappeared, and in thirty minutes from the time the tube was introduced the patient was sleeping quietly.

If this simple procedure proves inadequate, friction may be applied over and along the colon, as has been recently mentioned by Dr. A. E. Gallant. This complication, however, will seldom arise if, during the week preceding the operation, proper attention is paid to clearing out the intestinal contents. If the patient continues to do well and retains nourishment, and the intestinal canal has been well emptied, no cathartic need be administered until the third or fourth day, when one-tenth of a grain of calomel and one grain of soda should be given every half-hour for five hours. If the bowels do not act within three hours after all the calomel has been taken, a Seidlitz powder should be administered, and repeated after another interval of three hours. After the bowels have moved, if all has gone well, the pulse rate will be much as it was prior to the operation, and by the evening of the fourth day the bodily temperature should be normal, in which case the patient may be rapidly allowed to resume ordinary diet.

The dressings should be removed on the fifth day, and, if the sutures are beginning to cut the tissues, they should be removed and the wound supported by strips of adhesive plaster; otherwise they should be allowed to remain a few days longer. The dressings having been removed, the wound should be washed with hydrozone and bichloride solution, and freshly dusted with acetanilid powder before they are replaced. Before the sutures are removed, the wound and its surroundings should be thoroughly cleansed. A suture is then picked up at one side by means of a pair of thumb forceps, and the skin at the angle is depressed by the flat surface of a pair of scissors, the blades of which straddle the strand of gut, which is then cut through. The object of this manœuvre is to cut the portion of suture that has been buried in the tissues, and which is therefore clean, so that in dragging the gut through the deeper tissues and the peritoneal cavity the danger of infection will be reduced to a minimum. The patient should remain in bed for about eighteen days, and may then be allowed to sit up and soon thereafter to walk about and resume his ordinary occupation.

Complications.—The complications that may be encountered during the period of convalescence, and which change this ordinarily peaceful period into a more or less stormy and anxious one for both the patient and the physician, taxing the latter's ability to the utmost, occur in the following order: Concealed hemorrhage, peritonitis, intestinal paresis, intestinal obstruction, and stitch abscesses.

The occurrence of concealed hemorrhage, which fortunately at present seldom happens, especially when the vessels are tied with catgut taken directly from alcohol in which it is preserved, manifests itself during the first twenty-four hours by a rapidly rising pulse, decreasing in volume, and accompanied by a falling body temperature, dilatation of the pupils, and a clammy perspiration. When this condition is followed by a rapid rise of body temperature to 103° F. or over, dissolution is imminent. As soon as this complication is recognized, an intravenous injection of saline solution should be given and the patient stimulated by hypodermic injections of ether, whiskey, strychnine, and digitalis, and if there is a reasonable response the abdomen should be at once opened, and the bleeding point searched for and secured; otherwise the operation would prove useless and would only be an ante-mortem instead of a post-mortem examination. The decision as to the occurrence of hemorrhage and the necessity of reopening the peritoneal cavity should be made with deliberation, as the unnecessary performance of this operation may seriously endanger the life of the patient.

The onset of peritonitis is indicated by gradual but persistent rise of pulse, beginning on the second or third day, intestinal distention, and rigidity of the abdominal muscles, whether accompanied by elevation of body temperature or not. If the pulse rate rises and remains in spite of our efforts above 120 a minute, the outlook is generally unfavorable. As soon as this tendency of the pulse to increase in frequency after the first day is recognized, an effort should be made to move the bowels by the administration of calomel, followed by a saline. If this does not act in a reasonable time, another dose of calomel should be given, followed after an interval of several hours by another saline. A stimulating enema of seven ounces of a saturated solution of sulphate of magnesium and one ounce of glycerin is often very effective. If the bowels act freely our patient is generally safe, but if the symptoms persist instead of subsiding a few stitches should be removed from the abdominal wound, the cavity freely irrigated, and its contents cleansed in the manner recommended by Finney.

The advent of intestinal paresis is marked on the second or third day by distention of the abdomen and the occurrence of more or less persistent vomiting, the contents of the stomach being ejected without nausea, and the fluid being at first of a yellowish color, but not having a fæcal odor. As the color of this fluid darkens, the prognosis becomes less and less favorable. It is well to bear in mind that vomiting resulting from the administration of the anæsthetic subsides usually during the first twenty-four hours, but that it may follow the administration of morphine. When the diagnosis of intestinal paresis has been made, the stomach should be washed out and salines given at frequent intervals until the bowels act, even if the saline be partially ejected by the patient. The writer's efforts have been crowned with success in more than one instance by the persistent administration of salines after the patient's condition had seemed hopeless. The stimulating enema already alluded to should be given and friction applied over the colon. If the bowels act, the patient usually has no further trouble.

Intestinal obstruction, which fortunately has seldom or never occurred in those cases in which the writer has left saline solution in the general cavity, is differentiated from intestinal paresis by the pain over the site of the obstruction, more persistent vomiting, accompanied by nausea, the vomited matter having sooner or later a fæcal odor. This condition should be treated as soon as recognized by reopening the abdominal cavity, finding and freeing the constricted portion of gut.

Stitch abscesses usually announce themselves by the occurrence of a rise of body temperature toward the close of the fourth or fifth day, and should be treated by the application of hydrozone and the removal of the sutures. The opening in the skin should, if necessary, be enlarged to allow of the free evacuation of the pus.

While the various symptoms described have individually to be considered and their meaning weighed, they also have to be considered collectively, and in judging of the gravity of the patient's condition the facial expression is of great value to those who have had experience. A depressed and anxious countenance generally denotes a grave condition, and a cheerful one, even if accompanied by an elevation of pulse and tem-

perature, that the condition is not serious. The physician charged with the care of a patient upon whom a laparotomy has been performed should not think too constantly of peritonitis—that bugbear of all who have had little experience with abdominal work—and consequently feed the patient upon salines rather than with milk or soup. On more than one occasion the writer has known this fear to be the father of the thought, and the patient's life either sacrificed or convalescence needlessly prolonged by this error in judgment.

In closing this paper it is the writer's desire again to call attention to the points which he thinks of importance, and which, as they are considered minor ones, are often overlooked. They are as follows:

(1) The importance, whenever practicable, of prolonged preparatory treatment of patients about to undergo an abdominal operation.

(2) The importance of the administration of cathartics in the early part of this period, followed by large enemas for the purpose of cleansing the intestinal tract.

(3) The importance of keeping a record of the body temperature, respirations, and pulse rate, for several days in advance of the operation, and of making a final examination of the urine.

(4) The necessity in the female of arranging to have the operation performed a few days after the menstrual period, and the cleansing of the vagina, even when it is intended that the operation shall be by the abdominal route only.

(5) The administration of a small quantity of peptonized food (one ounce) containing stimulants, two hours before giving the anæsthetic, for the purpose of lessening the tendency to nausea and vomiting after the recovery of consciousness.

(6) The necessity of the anæsthetic being given by an experienced physician, and in the smallest possible quantity.

(7) The necessity of protecting the patient's body properly with clothing and blankets during the operation.

(8) The advantage of stimulating the pulse before the heart has become much exhausted, and of using intravenous saline injections before the radial pulse has become extinct.

(9) The leaving in the abdominal cavity after free irrigation of a quantity of hot saline solution, for the purpose of stimulating the patient, preventing (?) the formation of intestinal adhesions and lessening the danger of septic infection of the peritoneum.

(10) The necessity of making the patient comfortable by change of position during the first two days of convalescence, and by the use of the rectal tube.

(11) The necessity for the early administration of food in reasonable quantities and at proper intervals.

(12) The necessity of withholding stimulating enemata after operations in which extensive and firm pelvic adhesions have been broken up.

(13) The necessity for deliberation as to the wisdom of reopening the peritoneal cavity in a given case of supposed concealed hemorrhage.

(14) The importance of washing out the stomach as soon as the diagnosis of intestinal paresis is made, and of the persistent use of saline cathartics till the bowels move.

(15) The importance of not administering cathartics to those convalescing from abdominal operations, and who are pursuing a normal course, too early or in too large doses.

Castor Oil can be made more fluid by warming, and more pleasant to the taste by adding sugar or an equal quantity of syrup of manna.—Teixeira.

FAITH AS A REMEDY FOR DISEASE.

By ALBERT H. BURR, Ph. B., M.D.,

ADJUNCT PROFESSOR OF PRACTICE OF MEDICINE, [illegible] AND SURGEONS; ATTENDING PHYSICIAN, [illegible], CHICAGO.

The man of medicine, by reason of his training and experience, is in a large measure a materialist. From his entrance into the dissecting-room, on through his four years of laboratory experiments and observations in the clinics, he is dealing with the physical characteristics of matter and the pathologic showings of disease. Naturally he turns with much confidence to his materia medica and surgical resources, to his knowledge of the laws of hygiene, dietetics, exercise, change in occupation or environment, for his expedients in the cure of diseases.

As a rule he has overlooked the important relations of the mind to morbid processes, and is too apt to regard its influence in the cure of diseases as of minor or secondary importance.

It is not creditable to the intelligence of the great body of scientific physicians that so many of us ridicule or discredit the cures, some of which are genuine, wrought without the above-mentioned agencies through so called faith healers, Christian scientists, and the like. We cannot ignore entirely the testimony of those who have been relieved or cured of maladies by these methods.

It is time the medical profession acknowledged candidly that such things are possible and do take place in a certain class of patients and diseases. It is time it learned to account for and explain these results through the operation of well-known psychical laws.

Every physician should be prepared to show that there is nothing miraculous or supernatural about these cures. He should be able to demonstrate that the physician who devotes his life to the healing art can do all, and much more than this class of healers can do, no matter by what name they are known, without masquerading behind superstitions, simply by comprehending and acting upon certain principles of psychology and the laws which govern suggestion.

If any physician thinks it is not time for the profession to wake up on this subject, let him look at those great institutions of divine healing and Christian science on the prominent boulevards of our city. Let him visit them and see his patients and his neighbors' patients flocking to them, and consider if it is not worth his while to employ intelligently a much neglected means of therapeutics which some of these laymen employ ignorantly and often harmfully. Many of these healers are tricksters and mountebanks, like the recent false Schlatter. Others are sincere, but deluded as to the philosophy of the few cures they are able to bring about, which the intelligent physician knows are due to suggestion alone.

These various schools claiming to practise mental healing, faith healing, divine healing, Christian-science healing, may all be classed under the head of psycho-therapy, which is a division of suggestive therapeutics. The influence of suggestion upon the human mind is supreme and all-powerful in determining its own process of thought, its expressions of sentiment or passion, and its subjective control of bodily function in health or disease. It is through imitative suggestion that we yawn, cough, weep, or laugh, because we hear or see some one else doing so. It is through psychical suggestion that our emotions are deeply moved in reading fiction, poetry, or romance. It is by suggestion that a mother soothes the pain of her little child who has pinched its fingers in the door and runs screaming to her for aid. "Mamma will kiss the hurt all away. Now it doesn't hurt any more." The child believes its mother; the hurt is gone; its own faith has done the work; it dries its

tears at once and goes back contentedly to its play. That is faith cure and divine healing and Christian science in a nutshell. Again, the mother instinct knows her restless, wakeful babe needs sleep. She sings a soothing slumber song full of sleep suggestions and the babe closes its eyes in dreamland. That is hypnotism in a nutshell. Faith cure and hypnosis are both ruled alike by suggestion, and the mother, so far as child life is concerned, is the unconscious mistress of both. All we may hope to do in whatever form we employ therapeutic suggestion is to expand and improve upon her methods.

A man whose leg had been broken many months before came to the clinic of a prominent surgeon of this city by the aid of crutches, to learn why he could not walk. After a careful examination the surgeon said: "There is nothing the matter with your leg now; it is entirely healed. You are well and don't know it. Put down your crutches and try to use your leg." After a sorry effort the man, discouraged, begged for his crutches again. "No," said the surgeon, "you need a little Christian science; the trouble is in your mind more than in your leg. You must try again; you can certainly walk on it." With this the patient made a second trial with such good success that he concluded he could get along without the crutches. If this man had strayed into Alexander Dowie's healing temple down on Michigan Avenue, I have no doubt Dowie would have made a grand-stand play with the case. He would have commanded him to walk in the name of the divine Healer and to the glory of Brother Dowie and the plaudits of the multitude. The crutches would have gone to ornament the wall as another trophy of victory over the "doctor devils" who could not heal a poor cripple. Seeing is believing, and great is Alexander.

It is often impossible to eliminate the influence of suggestion, even in the administration of drugs, and say how much of the effect is due to drugs alone and how much is due to suggestion. To many people the strongest possible suggestion of cure centres about the idea of taking a medicinal drug. With such a person bread pills will sometimes work wonders. On this ground a placebo is often most beneficial. Doubtless we often take credit to ourselves for skill in the administration of what are really inert or useless drugs, when the cure is due entirely to *vis medicatrix naturæ plus vis medicatrix mentis*.

How, then, is faith cure related to suggestive therapeutics? I hope to show that it is in fact one form of suggestive therapeutics, though by no means its most effective form. Let us take Paul's definition: "Now faith is the substance of things hoped for, the evidence of things not seen." Hope is made up of desire and expectation. We cannot hope for what we do not desire, though we expect it certainly to take place. We cannot hope for what we do not expect, though we desire it greatly. Now ardently to desire and to expect a cure from some malady are certainly strong suggestions to that end.

Again, a faith that accepts unseen evidence must set aside judgment and all criteria by which one determines the truth or falsity of a proposition. What, then, do we have when one accepts a proposition as true by an act of faith? Is there not an abeyance of judgment and the critical faculties? This is just exactly what takes place when that peculiar psychical condition, hypnosis, is induced, in which susceptibility to suggestion is heightened. Judgment is asleep. The critical faculties are asleep, and the exalted imagination and subjective mind accept, *nolens volens*, whatever the operator chooses to impress upon them, without any argument or criticism to oppose.

When the suggestions in this induced state are directed to the wiping out of the mental perception of pain or of functional disturbances, we call it hypnotherapy, another branch of suggestive therapeutics, which latter in its broader significance embraces every method by which one may accomplish the cure of morbid conditions through psychical influences.

Hypno-therapy is the most potent of all forms of suggestion, and by its aid cures are accomplished frequently which seem little less than miraculous, did we not know the mental laws governing them. Just so, faith as a remedy acts through suggestion. It is purely subjective. It is, in fact, auto-suggestion, and needs no interposition of the supernatural to explain its phenomena.

When Paul and Barnabas went down to Lystra they beheld a man sitting there impotent in his feet, and Paul, "perceiving he had faith to be healed," commanded him "with a loud voice" to "stand upright." It was not Paul who had power to heal, but the subjective faith of the man stimulated to intense activity by the suggestive command of Paul. So with hypnotherapeutics. It is not effective through some mysterious influence or magnetic power of the operator, but through the subjective susceptibility of the patient to the operator's suggestions.

Why, then, are faith healing, divine healing, and Christian-science healing much more limited forms of suggestive therapeutics than those accomplished through hypnosis? Simply because they require the exercise of a childlike faith on the part of the patient, which is a *sine qua non*. He may be ever so desirous of a cure, but the slightest doubt will keep down expectation, and "the substance of things hoped for" is impossible to him. Hence it is clear that their benefits, potent or curative as they may be, are limited to the few who can comply with the terms. Hypno-therapy is far more universal in its application. The patient under hypnosis accepts suggestion as the little child accepts. Its judgment and critical faculties are undeveloped and inoperative; his judgment and critical faculties are just as impotent for the time being, for they are in complete abeyance. He has no means of doubting, and so the skilful physician through appropriate suggestions effaces his mental perception of a real or imaginary pain, or of a real or imaginary functional derangement, and relief or cure follows.

I venture the assertion, which is a profound conviction based on my own observations and the large number of published cases of eminent scientists like Bernheim, Charcot, Moll, Forel, Schrenck-Notzig, Krafft-Ebing, and others, that there have been no authentic faith cures (wrought by whatever method of suggestion, whether by laying on of hands, by anointings, by prayer, or by pilgrimages to famous shrines) which have not been, and cannot be, duplicated by suggestion under hypnosis.

The great danger to the public from those who may practise these various methods lies in the dogmatic ignoring of useful and ofttimes absolutely essential medical and surgical agencies. These so-called healers are grossly ignorant of pathology and physical diagnosis. They have little or no ability to discriminate between the classes of diseases which can be influenced or cured by suggestive methods (faith cure, Christian science, etc.) and those in which they are of little importance or utterly futile. Unable to distinguish between the disease itself and the pain impressions it causes, when they have removed the latter they announce the former cured. This misguided zeal and lack of medical knowledge of disease have cost health and life itself to many a client abounding in submissive faith, who otherwise could have been rescued by intelligent medical assistance.

To recapitulate, I have made the contention that faith as a remedy for disease is ruled by suggestion and is one form of suggestive therapeutics; that its

operation is purely subjective and dependent upon well-known psychical laws and not upon miraculous or supernatural intervention; that in its application it is much more limited and less available than another form of suggestive therapeutics termed hypno-therapy; and, lastly, that any authentic faith cure can be duplicated by hypnotic methods without any exercise of faith whatever.

100 State Street.

GALL STONES IN THE COMMON BILE DUCT RESEMBLING CARCINOMA OF THE STOMACH.

By FREEMAN F. WARD, M.D.,

NEW YORK.

It is a well-worn saying, and one the truth of which few have escaped realizing in life, that we learn more from our mistakes than from our successes. That this was not only my own experience in the case I am about to cite, but that it was equally instructive to several of my colleagues who saw it is my excuse for putting the facts before the profession at large, and if it shall lead to the relief of suffering under the same or similar conditions, through what is commonly called radical, but what I here call the most conservative treatment, I shall feel fully repaid for my pains.

April 24, 1897, Mrs. S——, aged forty-six years; weight, one hundred and fifteen pounds; mother of ten children, the youngest six years of age. She passed the menopause three years ago, and has always been healthy and strong until the present trouble appeared. For the past six months the patient has had more or less pain in the epigastrium, often sharp and shooting in character, coming on after eating, and being accompanied by extreme nausea which lasted from one-half hour to several hours. The patient states that the condition is always aggravated by the ingestion of albuminous food, such as meats and eggs, so that for the past three months she has lived almost exclusively upon a diet of bread and butter and tea. She has lost flesh and strength, looks emaciated, slightly jaundiced or cachectic; appetite very poor, tongue fairly clean, bowels regular.

Physical examination: Heart and lungs normal; abdominal wall very lax; lower border of stomach four fingerbreadths below the umbilicus, upper border about one fingerbreadth above the umbilicus. Pulsation of the abdominal aorta could be distinctly felt above the lesser curvature of the stomach. In the region of the pylorus a small tumor could be felt, which moved up and down with respiration, but was not freely movable by palpation.

Result of chemical examination of the stomach contents, expressed one hour after giving a test breakfast of one roll and a glass of water: Quantity, 90 c.c.; total acidity = 18; free HCl = 0; lactic acid = 0; considerable mucus.

Examination of the urine disclosed nothing abnormal.

I made the diagnosis of probable cancer of the pylorus, and determined to try to alleviate the patient's suffering, to have her assimilate more food if possible, and to build up her strength, with the end in view of advising an exploratory cœliotomy and in all probability a pylorectomy or a gastro-enterostomy. To this end the stomach was thoroughly washed out every second day three hours after breakfast. A stomachic of nux vomica with fluid extract of condurango was prescribed, and the patient told to eat three moderately good meals a day, to avoid meats, and to take between meals a glass of kumyss or milk.

The patient began at once to improve in appearance and to gain in strength, the appetite improved, and the pains became less frequent and less severe. Subsequent examinations were made, both physical and chemical, with practically the same results as at first, *i.e.*, gastroptosis, a palpable tumor, absence of free HCl, and no trace of lactic acid. There was some slight retention of food, but the amount of mucus diminished, due to the lavage.

Improvement continued until, on May 10th, I was hurriedly called and found the patient suffering excruciating pain in the epigastrium, with vomiting. There seemed to be no alternative at the moment but to give a hypodermic of morphine and atropine, which lessened the pain for several hours. I called the same evening, found a return of suffering, and administered ten grains of phenacetin, which gave almost immediate relief, and the patient passed a comfortable night. The next morning, as the patient seemed well enough to be moved, I advised her to go to the hospital and submit to an operation, to which she assented. The operation was performed by Dr. B. Farquhar Curtis.

Upon opening the abdomen by an incision in the median line above the umbilicus, the stomach was found to be in normal condition and of normal size, but displaced downward. In the common gall duct, however, could be felt quite a mass blocking it, which when the duct was opened by a linear incision proved to be two large impacted gall stones—one cuboid in shape, measuring 9 by 10 by 11 mm.; the other one not quite so regular in shape, but larger, measuring 15 mm. in length by 14 mm. at the small end and 17 mm. at the large end in diameter. These were removed; the duct was closed with Czerny-Lembert sutures, and the abdominal wound closed, except for a distance of about one inch, in which was placed a small strip of iodoform gauze for drainage. This was removed the third day, and recovery was complete and uneventful. The patient is now following her usual pursuits.

It may be interesting in this connection to report a case of true carcinoma of the stomach, which followed soon after in my practice, and which presented all the typical signs of the disease. The symptoms in common in both cases may then be compared.

May 29, 1897, Mrs. J——, aged fifty-three years. No children. Weight one year ago, one hundred and twenty pounds; weight now, ninety pounds. She has always been a healthy woman until six months ago, when she began having occasional attacks of pain in the epigastrium, which were aggravated by taking food, especially meats. Only recently the patient has had attacks of vomiting coming on soon after the ingestion of food. Appetite very poor, bowels constipated. Patient looks cachectic or jaundiced, and has lost flesh and strength.

Upon physical examination a small tumor could be felt in the pyloric region, moving up and down with respiration, it being possible to hold it down during expiration, showing that it was free and non-adherent to any other organ. Splashing sounds could be obtained three fingerbreadths below the umbilicus.

One hour after a roll and a glass of water were given, the stomach tube was introduced and the contents were expressed, with the following result: Quantity, 450 c.c.; very dark fluid, containing bits of meat, egg, fish, tomato, etc., some of which had been taken days before; a great deal of mucus. Reaction, acid; total acidity = 60; free HCl = 0; lactic acid = +.

The stomach was thoroughly washed out and the patient was prescribed a diet of milk, pea, bean, and vegetable soups, to be well cooked and strained; nourishment in some form was ordered to be taken every three hours. A mild stomachic was prescribed of nux vomica and condurango, and ten-grain powders of phenacetin to be taken when pains were severe.

On the third morning the patient reported having

had very little pain, no vomiting, and the appetite much improved. The whole appearance of the patient had changed from one of despair and despondency to that of hope and cheerfulness.

After a thorough washing of the stomach, one roll and a glass of water were given her immediately, which were expressed through the tube one hour later. Chemical examination showed: Total acidity = 8; free HCl = 0; lactic acid = +.

A diagnosis was now made, with almost absolute certainty, of carcinoma of the stomach, located in the anterior surface and lesser curvature, partially obstructing the pylorus. The location of the tumor was brought out by inflating the stomach with gas, produced by giving the patient a half-drachm of sodium bicarbonate and a half-drachm tartaric acid dissolved in a little water and given in separate draughts. By careful manipulation the gas could be felt passing through the pylorus below the tumor, but not above it. This point was observed by Dr. W. V. V. Hayes, who also saw the case, and this diagnosis was afterward confirmed at the operation.

As soon as the above treatment was established, a marked improvement was observed in the patient. She gained in strength, the appetite improved, and the bowels became regular without the aid of laxatives or enemas. I knew, however, that this improvement could only be temporary, and advised her to go into a hospital and submit to an operation, to which she consented. For a few days before the operation she was given nutrient enemas in addition to food by the mouth. Dr. C. N. Dowd and I performed the operation of gastro-enterostomy, after the so-called Wölfler method, without the use of plates or button.

The abdominal cavity having been opened by an incision in the median line above the umbilicus, the tumor was found in the exact position as diagnosed, freely movable, so that it could be lifted out of the abdominal cavity. The stomach was dilated and in a position of gastroptosis. Glandular involvement was very slight —indeed, at first it was thought there was none, and a pylorectomy was seriously considered; but after a careful search a few small glands were found to be involved, and this fact, together with the weakened condition of the patient, decided the question in favor of the less severe operation of gastro-enterostomy. A loop of intestine about two feet below the pylorus was given a half turn on its axis, and laid on the anterior surface of the stomach near the greater curvature at a safe distance from the tumor, and the two were united with interrupted sutures of fine silk for a distance of two and one-half inches. An incision was then made into both stomach and intestine, about one and one-half inches long, one-fourth inch from the line of sutures. The raw edges were united the entire distance around with fine catgut, and then the outer row of silk sutures was continued anteriorly, thus completely inclosing the inner row of catgut sutures. The abdominal wound was closed and the patient left the operating-room in good condition.

She was given nutrient enemas for three days, and on the third day she began taking nourishment by mouth, but on this day she began to develop symptoms which proved to be on the fifth day a typical lobar pneumonia. She died on the ninth day after the operation, of pneumonia, having had no distention or vomiting and having retained all food and medicine.

The point which I wish to emphasize in connection with these two cases is the importance of careful and repeated examinations, both physical and chemical, in all disturbances of the stomach, and also, in all doubtful cases, of making an early exploratory incision, followed by such operation as may be indicated.

In this first case there seemed scarcely a doubt that the patient was suffering from carcinoma of the stomach, and I must add that after I had examined her myself three excellent diagnosticians confirmed my decision; yet it would have been not only radical but cruel to use palliative treatment only, when trouble existed which proved to be perfectly amenable to surgical procedure.

In the second case, as there were present all the typical signs and symptoms of carcinoma, it would seem that if careful and repeated physical and chemical examinations had been made early in the disease —and she had consulted a number of physicians from the very beginning of her trouble—one could hardly have failed to make a correct diagnosis, and her life might have been saved, at least for several years. This case, in the hands of a surgeon three or four months before, would have been most favorable for a pylorectomy, with every chance of recovery. Even in the stage in which I found the patient I felt perfectly justified in advising an operation, which, if she survived, would relieve much of her suffering, enable her to gain in flesh and strength, and to enjoy life at least several months longer. Above all, she would be spared one of the most horrible deaths, that of starvation.

In conclusion, it may be of interest to some physicians briefly to review a few of the important points in the determination of carcinoma of the stomach, and some of the simpler methods of examination.

In the first place, I believe it is now generally conceded that the absence of free HCl in the stomach contents is in no way characteristic of carcinoma, as was formerly thought.

I have mentioned the aversion on the part of these patients to meat or albuminous food, which point I inquired into very carefully, as Boas, in the last edition of his book, referring to the investigations of Müller and Klemperer, says that the more albumin we give to the infiltrated organ the more decomposition we have, and that the attempt to compensate for the destruction of albumin by the more abundant giving of albuminous food is to be received as an illusion, and that herein exists the frequently observed fact that the patient has an instinctive aversion for albuminous food. I have noticed this symptom in the majority of cases of acute and chronic gastritis which have come under my observation, when there was an absence of free HCl, and this would tend to show rather that nature is averse to taking food which she cannot well digest than that it is in any way a distinctive symptom of carcinoma. We also find this secretion wanting in certain neuroses and in that class of cases in which there is no stomach secretion, called by Dr. Max Einhorn "achylia gastrica," of which I have had three cases in my private practice within the past six months.

It should also be stated here that the presence of free HCl does not exclude the possibility of carcinoma. The simplest tests for free HCl are: 1. Congo paper, which turns a deep blue if free HCl is present. 2. Günzburg's reagent, the formula for which is:

Phloroglucin	2
Vanillin	1
Absolute alcohol	30

Put a few drops of the filtered gastric juice in a small porcelain dish, add one or two drops of the reagent, and evaporate over an alcohol flame. Upon cooling, a bright rose-red will appear if free HCl is present. These two tests are all-sufficient for determining the presence of free HCl, and can easily be made before the patient leaves the office. Quantitative determination should also be made, but it is not my purpose to go into the more elaborate methods of analysis in this article.

The presence of lactic acid in the stomach contents has greater significance. While the secretion of lactic

acid does not usually occur in the healthy stomach after the ingestion of carbohydrates, yet it does sometimes take place in innocent affections of that organ, *i.e.*, gastritis, ectasia, atony, neuroses, etc.; moreover, the production of lactic acid does not usually occur when free HCl is present; thus it would appear that the clinical examination thus far has neither theoretical nor practical value. In exceptional cases lactic acid may be lacking and therefore does not exclude carcinoma, but it has come to be regarded, taken with other symptoms, as a specific sign in the diagnosis of that disease. Frequently one may find the production of lactic acid and the lack of free HCl with stagnation of food in the stomach; hence the importance in such cases of thoroughly washing out the organ and giving a test meal in a clean stomach before determining whether the stomach actually secretes lactic acid or not.

The test which I use uniformly is Uffelmann's. The solution must be freshly prepared each time as follows: To 5 c.c. of a four-per-cent. solution of carbolic acid add 25 c.c. of water and two or three drops of tincture of chloride of iron. Fill a test tube about one-half inch with this solution, which is amethyst-blue, and add an equal quantity of the filtrate. If lactic acid is present the solution will change at once to a canary or lemon yellow. If any doubt arises, as sometimes will if phosphates are present, take 5 or 10 c.c. of the filtrate in a test tube, add double the quantity of ether, and shake thoroughly. Then allow the tube to stand a few minutes until the ether separates from the solution. Pour off this ethereal extract and test it for lactic acid with the Uffelmann solution. It is well to make the test with a highly diluted solution of lactic acid in another test tube for comparison, until one becomes thoroughly familiar with the color.

I may say, then, that when we find these five conditions constantly present—*i.e.*, 1, stagnation of food in the stomach; 2, vomiting; 3, pain; 4, absence of free HCl; 5, presence of lactic acid—and, we might add, a short history of the disease, the diagnosis of carcinoma of the stomach can be made with almost absolute certainty, even in the absence of a tumor.

There is a large number of cases, however, which do not give all of the foregoing symptoms; hence the importance of careful and perhaps repeated chemical examinations of the stomach contents in disease of that organ, and, in doubtful cases which seem to point to malignant disease, of an exploratory laparotomy.

In the two examples cited, we found in Case I. some stagnation of food, vomiting, pain increased by ingestion of food, absence of free HCl, and a palpable tumor. In Case II. we found all the cardinal symptoms of carcinoma: 1, pain, increased by ingestion of food; 2, stagnation of food in the stomach; 3, vomiting; 4, absence of free HCl; 5, presence of lactic acid; 6, a palpable tumor.

In both cases the history was of short duration. In both there was slight jaundice or cachexia, between which it is often perplexing to differentiate. The serious consideration of these two cases would seem to indicate that, notwithstanding the fact that Case II. terminated fatally from pneumonia (which no one could have foreseen), the right procedure was followed for the best interests of the patients, and one life at least was saved.

6 East Fifty-Eighth Street, August 1, 1897.

Painful Fissure of Anus.—Dr. Doumer recommends, in *Le Scalpel*, October 31st, the introduction of an electrode through the whole length of the sphincter and the application of a current of high frequency. This has also been found to act favorably upon hemorrhoids and to cause shrinkage of hemorrhoidal tags.

Clinical Department.

A CASE OF CEREBRAL ABSCESS.

By H. H. WEIST, M.D.,

The diagnosis of most of the intracranial diseases amenable to surgical treatment is often difficult, and in none of them more so than in those following traumatism after a long interval. It is true that, owing to the labors of Ferrier, Horsley, and others, during the last decade, which have given the profession the well-recognized facts of cerebral localization, many of the difficulties have been removed in cases in which the injury involves the motor tracts; yet the fact remains that many intracranial conditions cannot be determined with certainty, probably for the reason that the precise function of comparatively large areas of the brain is still unknown. We are, indeed, yet unable to place the precise boundaries to the best-known motor tracts.

To show in a clear light how the present knowledge of the functions of some of the areas of the brain may guide the surgeon to a correct diagnosis, I briefly report the following case:

On June 15, 1897, with my father—Dr. J. R. Weist—I saw, in consultation with Dr. R——, Mr. B——, aged thirty years. We received the following history of the case:

The patient was a farmer, unmarried, who had always been healthy; there was no history of any constitutional disease, or of any accident. Three weeks before, he was seized with a severe pain in the head followed by vomiting. Dr. R—— was the sixth medical man who had been in attendance on the case, the patient being unconscious when first seen by him. We were unable to learn any particulars as to special location of the pain. Pain in the head with vomiting and some fever continued for about a week. The case at that time was diagnosed as one of typhoid fever. About this time numbness was complained of in the left hand and left foot; this continued, gradually involving the entire arm and leg; then loss of motion gradually appeared, following the same order; then dizziness and some incoherence appeared. All these symptoms grew more severe until the end of the second week, when there was complete paralysis of sensation and of motion in the entire arm and leg, with entire abolition of intelligence. In this condition he had remained almost unchanged for a week preceding our visit. Two days before, Dr. R——, thinking he had found some evidence of an abscess, had made a slight puncture in the scalp just above the right ear, with a negative result.

We found him in a comatose condition; temperature normal; pulse feeble, regular, 70 to the minute; respiration very shallow; pupils unresponsive to the light, the right slightly dilated; complete paralysis of the left arm and leg. Pinching the right arm and leg and tickling the sole of the right foot caused slight reflex action. No history of any form of injury to the head could be obtained.

It will be seen that we were unable to obtain a complete history of the case.

The sudden onset of the disease and the absence of all the characteristic symptoms enabled us at once to exclude typhoid fever as the disease present; while the pain in the head and the vomiting might indicate meningitis, and this complication is sometimes present in typhoid fever, the progress of the case excluded this condition. The paralysis on the left side made it evident that the lesion of the brain was on the right side, and the dilated pupil on the right side indicated the same thing.

The paralysis extending from the left hand gradually to the entire arm, then from the left foot to the leg, made it evident that the lesion of the brain, whatever it was, began in the lower and posterior part of the middle third of the anterior and posterior central convolutions, which border the fissure of Rolando, these parts governing the motion of the hand. The extension to the entire arm and leg also made it clear that the disease gradually extended to the upper third of the same sensori-motor convolutions.

While local meningitis might have preceded the evident lesion of the anterior and posterior central convolutions, clinical observation does not show that it might have caused the same. There was no history of syphilis, therefore gummata might be excluded; besides, these growths do not appear suddenly. All other forms of brain tumor, also, are of slow growth, and cause a long series of symptoms before culminating in so serious a disaster as had befallen this patient. Tumors of all sorts being excluded, there remained only some form of acute inflammatory action to account for the symptoms present. The age of the patient, and the order in which the symptoms appeared, excluded the idea that blood had been poured out from a ruptured artery, causing softening from pressure or inflammation. There was no disease of the heart, no vegetation to be washed into the general circulation to form an embolus in one of the cerebral arteries, to be followed by inflammatory disintegration. There had been no sepsis to cause a pyæmic abscess. By exclusion the diagnosis of an abscess involving the sensori-motor centres of the left arm, probably the result of an injury to the head, was reached.

The case being an urgent one, the statement was made to the friends of the patient that only an operation, trephining over the supposed seat of the disease, gave any promise of relief—the exact statement made being: "He will die if the operation is not made, and probably die if it is." The operation was declined, the father saying he "would trust him a while longer to the Lord." Three days later—the Lord in the mean time having failed to perform any miracle on the patient—we were again called. He remained in essentially the condition before described. We were informed that it had been learned that five weeks before the beginning of his illness the patient while working in a pigpen received a slight blow of some kind on the head. The part of the head injured could not be learned. He continued at work for *five* weeks, and the apparently trivial injury had been forgotten, until recalled by our inquiry.

Consent to the operation was now readily given. The patient being extremely weak, strychnine and morphine were given hypodermatically. The scalp was shaved and made as aseptic as possible. Careful examination revealed no cicatrix or other evidence of former injury, save the unhealed puncture above the right ear, made by the doctor when searching for pus a few days before.

The fissure of Rolando having been located by the usual measurements, Dr. J. R. Weist proceeded to the operation. A large flap—its base downward—was raised, laying bare the portion of the skull overlying the middle of the fissure of Rolando. When the very free hemorrhage from the scalp was checked, there was found in the parietal bone, two and a half inches above and one inch in front of the external opening of the auditory canal, an opening through the bone just large enough to admit a fair-sized probe. This evidence of former injury so positively confirmed the diagnosis that there was no hesitation about proceeding with the operation. An inch and a quarter trephine was placed at a point supposed to represent the middle of the Rolandic fissure, and when the circle of bone was removed the bridge of bone separating the opening from the perforation described was taken away with the rongeur forceps. The membranes had been perforated, but the wound had closed. The dura, much reddened, projected strongly into the opening of the skull. When this membrane was divided a branch of the middle meningeal artery was cut, causing very free hemorrhage. The vessel was ligated without much difficulty. The portion of the brain pressing strongly into the opening was without pulsation. It was identified as being a part of the posterior central convolution. The part of the brain visible presented nearly a natural appearance. No pus was seen. There being positive evidence of pressure from below, a knife was pushed into the brain substance to the depth of about an inch in a direction slightly upward. Then pus and broken-down brain substance were for the first time discovered. The quantity escaping was not great. Further interference being deemed unwise, the patient being in an extremely critical condition, an iodoform gauze strip was placed in the opening so as to lead out at the lowest part of the scalp wound. The flap of scalp was replaced, and the wound closed save at the point of emergence of the drainage. The usual aseptic dressings were applied. Directions were given to keep the drainage channel well open by replacing the strip of gauze from time to time.

At the close of the operation, the patient was greatly exhausted by hemorrhage and shock.

We have not seen the patient since, but have had frequent reports from the careful physician in attendance. From him we learn that the patient soon rallied from the operation; that on the next day consciousness was fully restored, and the paralysis of the arm and leg had nearly gone. He continued steadily to improve until the eighth day, when the coma and paralysis rather suddenly returned. Upon examination it was found that the drainage channel was obstructed; when this was cleared several ounces of pus was discharged, and then all unfavorable symptoms disappeared to return no more. From this time onward the progress toward recovery was uneventful. A report from the patient was received September 4, 1897, to the effect that the wound was entirely healed, with the functions of speech and of the arm and leg entirely restored; the only remaining evidence that the functions of the brain are not completely restored being an indifference to exercise or to work.

We have not learned if the patient remembers having received an injury. From all the facts it is safe to infer that the wound in the skull was made by a small nail. The length of time between the injury and the appearance of any serious symptoms—five weeks—furnishes another illustration of the well-established fact that injuries of the head, even when involving the brain, may give rise to serious trouble only long afterward.

The diagnosis of typhoid fever was evidently made without a proper study of the case.

To Prepare Catgut.—Originality is claimed only for the combination in the following:

R Potassii bichl	gr. i.
Formaldehyde	℥lx.
Aquæ	℥ i.

A good quality of gut is placed in ether for twenty-four hours, then washed in alcohol, wound upon glass spools, and put into the above solution for twenty-four hours. It is then to be stored in pyoktanin solution (1 to 1,000). Thus prepared it is aseptic, antiseptic, non-absorbable for from ten to forty days, while its tensile strength is not impaired. Rinse in sterilized water before using.—W. D. Jones.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 22, 1898.

THE MODERN NOVELIST AND MEDICAL SUBJECTS.

ERRONEOUS statements on medical subjects are very frequent in the modern novel, and appear to be becoming more so. Impossible and contradictory descriptions of the symptoms and course of a disease, together with a display of ignorance of medical matters in general, are a feature of up-to-date fiction. One would imagine in this age of realism that writers would try to be fairly accurate, or at least not make glaring mistakes. The latest literary production emanating from the fertile and imaginative brain of Mr. Hall Caine is a startling example of this slipshod tendency on the part of modern romancists. "The Christian" has raised a storm of criticism on all sides. Its accuracy as to details has been severely questioned, both from a lay and from a medical standpoint, and certainly the misstatements to be found in the work in respect to matters medical are extraordinary and amusing. The word pictures of hospital life and of a nurse's duties as portrayed in the description of Nurse Glory, while exhibiting the author's powers of imagination in a favorable light, also tend to show that his real knowledge of the subject is very little. To one who is acquainted from practical experience with the internal management of large hospitals, the accounts of the doings therein as set forth in "The Christian" will appear wonderfully funny. The entire book, indeed, is full of amusing perversions of medical knowledge, of which perhaps the most comical is Mr. Caine's definition of a stillborn child as one that has breathed but never cried.

The writer of fiction of the present day does not appear to advantage with many of the novelists of the past generation in his acquaintance and handling of medical subjects, although it must be confessed that even among the dead giants of romance there were but few whose description of a disease was absolutely correct. George Eliot is without doubt entitled to first place in this list; her sketches of doctors and her statements in regard to the diseases of which she treats are drawn with a masterly hand, and are as accurate as if written for a medical text-book. Charles Kingsley, again, in "Two Years Ago," traces the history of a cholera epidemic with the utmost attention to technical minutiæ. Thackeray also described the course of a malady as correctly as he did the treatment pursued by the physicians of his time. Of modern novelists, Besant, in the "Ivory Gate," gives an interesting study of an obscure brain disease, and as he informs us in the preface that he procured his medical information from a competent doctor it may be taken for granted that his statements are correct. Putting on one side, however, the comparatively few instances in which the diseases dealt with by novelists are to be depended upon as being correctly described, the majority of the medical statements in fiction can be divided into two classes: those in which the accounts of diseases given are false in every respect; and those in which the author, not being *au fait* with his subject, is careful not to commit himself, and therefore wisely confines himself to vague generalities.

Another point worthy of notice is the small number of diseases brought into the service of the novelist. At one time brain fever was the universal favorite, with typhoid a good second, and although within recent years neurosis has to a certain extent banished brain fever from its proud position, yet the latter disease still holds its own in fiction. That nervous prostration is much more likely to attack the hero or heroine suffering from the storm and stress of life, as depicted in the ordinary modern novel, than is brain fever, cannot be denied. Nevertheless, there are occasions when an author, in order to extricate himself from a complicated situation, is compelled to fall back upon a disease of an acute nature; and in such a predicament, what so suitable as brain fever or what so convenient as its delirious ravings? The fact has been more than once pointed out that there is a disease which has been strangely overlooked, and which certainly deserves to find more favor in the eyes of the novelist than has hitherto been the case. This complaint is pneumonia, for, while it fulfils all the conditions required by the novelist, and to a fuller extent than brain fever, it has none of the disagreeable associations connected with typhoid. Pneumonia may be termed an aristocratic disease, while typhoid, though no respecter of persons, still has a certain plebeian flavor savoring of foul-smelling drains and tainted water. In novels acute diseases invariably end suddenly. Pneumonia terminates by crisis; the onset of the attack is sudden, the temperature is always high; delirium, stupor, or complete unconsciousness is a feature in its progress. Thus in this disease there is a choice of dramatic climax found in no other malady. A wicked man can be cut off in the midst of his sins, or a good one can be made to provide an edifying death-bed scene. Pneumonia may be recommended to authors as a disease whose merits as an aid to fiction have not as yet received the appreciation from them which is undoubtedly its due. Consumption is a disease of such a nature that most novelists fight shy of it and are very chary of relating its tedious course. William D. Howells, in his latest work, has been bold enough to introduce a family all of whose members but one are afflicted with phthisis; and Gilbert Parker, in an interesting book he has lately written, has succeeded in rendering his consumptive hero a most fascinating and

attractive personality. In connection with consumption in fiction, it is instructive under the present circumstances to note that Smollett, more than one hundred and fifty years ago, draws attention in "The Expedition of Humphry Clinker" to the prevailing opinion then existing that consumption was contagious. Heart disease is naturally a favorite with writers of romance when a character gets rather too obtrusive and it is deemed advisable to remove her or him from the scene. Marion Crawford, in a "Rose of Yesterday," has drawn a graphic picture of the life and death of a fast man; but the most powerful sketch of the stages of syphilis was that of Samuel Warren, entitled "Man about Town," included in his "Diary of a Late Physician." In present and past fiction too many examples have been afforded of the manner in which eminent writers can err when they enter upon descriptions of technical matters without taking the trouble to verify their statements. It cannot be expected of a novelist, however talented he may be, that he should be conversant with a disease by mere intuition, and if he trusts to his imagination and to some superficial observation he will surely fall into grievous errors. When an author is distrustful of his medical knowledge, he should follow in the footsteps of the great masters of his craft, and either, like Dickens, touch upon such matters vaguely, or, better still, like Thackeray or George Eliot, obtain his information at first hand.

THE REPORT OF THE VISITING COMMITTEE OF THE DEPARTMENT OF PUBLIC CHARITIES ON THE HOSPITALS OF NEW YORK CITY.

The twenty-fifth annual report of the New York County visiting committee for Bellevue Hospital and other public institutions has lately been published. As it is also the first report covering the operations of an entire year of the department of public charities as now constituted, a special interest is attached to it. The new system, whereby the sphere of supervision of the commissioners of public charities has been restricted to the consideration of the conditions and needs of charitable institutions only, is a departure greatly to be commended. Under the former method the work put upon the shoulders of the commissioners was more than they could well bear. Much of the present report is pleasant reading, showing that an advance has been made in the right direction; but it also reveals the fact that many of the old abuses are still in existence.

In the first instance, it is satisfactory to note that the building-operations in the various institutions in the department are on a large scale and for the most part being pushed forward expeditiously. This step has not been taken before it was needed, as many of the buildings have been for several years in a dilapidated state, besides not providing adequate accommodation. Owing to the increased appropriations for current expenses, various improvements in the general administration of these institutions have been rendered possible. Prison labor has been to a large extent abolished in favor of paid help, the staff of paid employees has been augmented, and the food supplied to the patients has been better in quality as well as larger in quantity.

The committee, however, states that there is room for further improvement in this last respect. This is the bright side of the picture; now for the reverse.

The ward for male prisoners at Bellevue Hospital remains in its former insanitary condition, and is, according to the committee's report, a standing disgrace to the department. The quality and amount of the food given to the patients are described as insufficient, and the inferior manner in which it is cooked and served is also severely criticised. It appears that the allowance of meat for each patient at Bellevue should be eight ounces of meat once a day, but it is stated that barely five ounces is supplied. The doctors, superintendents, apothecaries, and nurses not only receive a daily allowance of twelve ounces, but also get the best pieces. Consequently the patients, instead of having their rightful allowance of eight ounces, get but five ounces, and this of inferior quality. Complaint is also made of the lack of ward supplies at Bellevue. At the City Hospital many alterations for the better have been introduced, both in regard to the building itself and its mode of management. The additions to the structure will when completed relieve the present pressure on its holding-capacity, and paid help has been substituted for prison labor. The Metropolitan Hospital suffers from serious overcrowding, and the building in hardly any respect fulfils the requirements of a modern hospital. The administration is commented on very favorably. There is one feature common to all the above-mentioned institutions, to which the committee rightly draws particular attention—that is, the present custom of scattering phthisical patients promiscuously through the wards. On October 1, 1897, there were eleven phthisis patients in the Bellevue Hospital, fifty-six in the City Hospital, and ninety in the Metropolitan Hospital. This state of things should be changed as quickly as possible, for, even granting that the contagiousness of consumption has been exaggerated, there yet remain many cogent reasons in favor of isolating its victims.

The most depressing part of the report is that which relates to the children's hospitals at Randall's Island. The death rate at the Infants' Hospital shows no decrease from the high figures of former years. The fact is well known to medical men that where infants are massed together in large numbers their chances of living are immensely diminished. Convincing proofs of this have recently been afforded in the case of the foundling hospitals in Italy and France. When the conditions are most favorable, babies without their mothers are liable to succumb quickly, but that the present appalling mortality at the Infants' Hospital on Randall's Island could not be considerably lessened with care and proper nursing will be believed by no one. Of three hundred and sixty-six infants admitted when under six months of age, without their mothers, during the year 1896, but twelve remained alive on April 15, 1897—a mortality rate of 96.1 per cent. The average duration of life of the three hundred and

fifty-four children who died was between five and six weeks. This fearful death rate is undoubtedly due to the incompetence or neglect of the nurses. The recommendation of the committee, that the number and salaries of the nurses should be increased, a nurses' home built, and that an expert supervising nurse should be placed in charge, would appear under the circumstances the most humane course to adopt. The State acts *in loco parentis*, but up to the present she has proved herself a very indifferent fostermother, sadly neglectful of her maternal duties. The committee remarks, with truth, that in every branch of its work the department of charities should be managed without regard to political considerations, and that it may be asserted almost with certainty if this were done all the needed improvements would follow. The city of New York is now the second in size and wealth in the world; in the intelligence and enterprise of her inhabitants she is probably the first. It is therefore by no means to her credit that such evils should be possible within her borders.

SIR JAMES SAWYER ON HUMAN LONGEVITY.

Sir James Sawyer has recently been lecturing at Birmingham, England, on the subject of human longevity. He lays down nineteen rules, which, he asserts, if followed closely, will prolong human life by many years. These rules are as follows: 1, Eight hours' sleep; 2, sleep on right side; 3, keep your bedroom window open all night; 4, have a mat to your bedroom door; 5, do not have your bedstead against the wall; 6, no cold tub in the morning, but a bath with temperature of the body; 7, exercise before breakfast; 8, eat little meat and see that it is well cooked; 9 (for adults) drink no milk; 10, eat plenty of fat, to feed the cells which destroy disease germs; 11, avoid intoxicants, which destroy those cells; 12, daily exercise in the open air; 13, allow no pet animals in your living-rooms—they are apt to carry about disease germs; 14, live in the country if you can; 15, watch the three D's—drinking-water, damp, and drains; 16, have change of occupation; 17, take frequent and short holidays; 18, limit your ambition; 19, keep your temper.

Some of these rules will commend themselves by their obvious common sense to every one; some are contrary to common sense; while, as to the remainder, the ordinary individual will be quite unable to keep them. Old persons as a rule cannot sleep eight hours. Sleeping on the right side will not suit all persons. Allowing the window to be kept open all night would most certainly be harmful to the health of many people. A very large number of persons would be only too glad to have change of occupation, as well as frequent and short holidays; opportunity is the sole thing lacking. "Limit your ambition" is altogether too vague a term to be thoroughly comprehended. In fact, the old English saw, "Keep your bowels open and wear flannel next your skin," if strictly adhered to, would probably be as conducive to longevity as following the nineteen rules laid down by Sir James Sawyer.

"THE LANCET" ON ANASTOMOSIS.

The Lancet, as is its custom at the end of the year, reviews at some length, in its issue of December 25, 1897, the events of the *annus medicus*. Referring to surgery, the writer says: "During the past year the progress of surgery, if not so exceptionally great as in some other years, has yet been evident. In the surgery of the abdomen the question of the best method of uniting a divided bowel is still unsettled. Murphy's buttons, while not perhaps retaining all the favor which they had on their first introduction, are still looked upon by many as on the whole the safest as unquestionably the most rapid means of effecting internal anastomosis. That some at least of the unfortunate results which have followed the use of the button have been due to its incorrect application is extremely probable, as the best results have been obtained by those who employ it most frequently. One danger from the use of the anastomotic button is the tendency it has to remain in the bowel. This has happened many times, and generally without ill effect, but occasionally symptoms of intestinal obstruction have resulted. To obviate this danger, Dr. Martin Gil, of Malaga, has devised a button which resembles Murphy's in some respects, but it consists of decalcified bone, so that it can be dissolved by the digestive juices after it has accomplished its work of uniting the bowel. Dr. Gil has employed the method with success in dogs, but the button has not yet been used in the human body. Those who decline to avail themselves of an anastomotic button either employ some form of 'bone bobbins,' such as that invented by Mr. Mayo Robson, or trust to simple stitching without mechanical aids. The fact that every one of the methods mentioned gives excellent results and is extensively employed shows that a skilful and experienced surgeon can safely unite divided intestines by any of them, and that he may be expected to attain the greatest success by using that method with which he is most acquainted. Even in the future we must not look for a complete discarding of any of these methods."

CONCERNING SLEEP.

Much has been written lately concerning the phenomena of sleep. Many persons have aired their views on the subject. Some assert that people as a rule sleep too long, while others are of the opposite opinion. Dr. Andrew Wilson has recently made some *à-propos* remarks on the matter. He first cites instances of celebrated men who needed a small amount of sleep, and says: "Humboldt, who lived to be eighty-nine, is said to have declared that when he was young, two hours' sleep was enough for him, and that the regulation seven or eight hours of repose represented an unnecessary prolongation of the time of somnolence. It is also said that Sir George Elliot, who commanded at the siege of Gibraltar, never indulged in more than four hours' sleep while the siege lasted, and that little affair occupied at least four years. Sir George died at the age of eighty-four. Dr. Legge, professor of Chinese at Oxford, who died the other day at the age

of eighty-two, was declared to be satisfied with five hours of sleep only, and rose regularly at 3 A.M. What do such cases prove? Assuming the correctness of the details, they prove only that certain men (and very few men, I should say) are able to recuperate their brain cells more quickly than the bulk of their fellows. They are the exceptions which, by their very opposition to the common run, prove the rule that a good sound sleep of seven or eight hours' duration represents the amount of repose necessary for the average man or woman. It would be a highly dangerous experiment for the ordinary individual to attempt to curtail his hours of repose, and it must not be forgotten that in this matter of sleep we have to take into account the question of the daily labor and the nature of the work in which the individual engages. In the case of Dr. Legge we have a picture of the student whose labor is solely of the intellectual kind, involving little drain on the muscular system. In the case of Sir G. Elliot we have an active commander, who, in addition to the mental anxieties involved in the conduct of a long siege, had no doubt a fair amount of physical exertion to undergo. But, while the case of the professor may be explicable on the ground that his five hours' sleep compensated him for any wear and tear his quiet life presented, we may fall back in the instance of the general on the theory of a special organization, set, as it were, so as to satisfy itself with a limited amount of sleep. The personal equation, in short, plus the kind or character of a man's work, determines the duration of his repose; and that the average period required by the ordinary individual in health is from seven to eight hours is the one opinion confirmed by the collective experience of the civilized race."

News of the Week.

Beriberi in Port.—The bark *Pactolus*, which arrived here on January 13th from Manila, brought in twelve cases of beriberi among her crew of sixteen sailors. Two of the men have died since the vessel came into port. The sailors were taken on at Shanghai, and it is thought some of them were suffering from the disease at the time they shipped.

Triplets.—The wife of an Austrian tailor in this city recently presented him with three healthy girl babies at one birth. The father is reported to be more proud than pleased.

The Plague.—The deaths from bubonic plague at Bombay during the week ending January 13th were 450. The deaths from all causes during the same period numbered 1,307.

The Late Dr. A. W. Stein.—The following resolutions were adopted by the board of trustees and directors of the New York College of Dentistry at their regular monthly meeting on January 3, 1898:

"It is with deep regret that the New York College of Dentistry is called upon to mourn the loss by death of the late Prof. Alexander W. Stein, M.D., who for twenty-eight years served the college with marked ability as professor of physiology, visceral anatomy, and histology, and who for twenty-one years occupied the office of treasurer, in which position he discharged his duties with diligence and faithfulness.

"Honored by his associates in the faculty and in the board of trustees; respected by the medical profession, both in this country and abroad, for his many valued contributions to surgery; and beloved by a large number of students who have listened to and profited by his teaching—he has passed away a martyr in the cause of science, as his health was undermined by the effects of a poisoned wound received while operating for charity in one of our city hospitals.

"Failing health caused his resignation, two years since, from the active duties of his professorship, and his death, while not unexpected, is a loss to science and a source of sincere regret to the college with which he has been so long connected.

"We tender our heartfelt sympathy to the members of his family, and mourn with them a loss which cannot be expressed in words.

"*Resolved*, That this record be spread in full upon the minutes of the board of trustees of the college, and a copy forwarded to his family and to the medical journals of this city.

"J. Bond Littig, D.D.S.,
"F. Le Roy Satterlee, M.D., Ph.D.,
"*Committee on Resolutions.*"

The Yellow Fever in Jamaica.—It is reported from Kingston, under date of January 4th, that the outbreak of yellow fever in the island has abated, except at Up Park Camp, about a mile outside of Kingston in the Liguanea Plain, where the British troops are stationed. In Kingston and other towns no new cases have occurred, and it is hoped that in a few days the entire island will be declared free. It has been found necessary to move the troops out of the barracks at Up Park Camp and put them in tents, while the officers have taken up their quarters in a private house some distance away.

Improved Sanitary Conditions in the German Army.—The health statistics of the German army, which have just been published, show that in the past thirty years, from 1868 to 1897, the cases of illness fell forty-two per cent.—that is, that now about twenty-three thousand fewer men fall ill every year than formerly. During that same period the mortality decreased sixty-five per cent.—that is, during their time of military service twenty-two hundred fewer men died.

Anesine is the name of the latest rival of cocaine in the production of local anæsthesia. Its use is said to be devoid of local or general toxic effects.

Removal of the Stomach.—Since the publication of Dr. Schlatter's case of total exsection of the stomach, which was reported in the Medical Record of December 15th last, two operations of the sort have been undertaken in this country—one in St. Louis and the other in Milwaukee. In each instance the patient died a few hours after the completion of the operation.

Influenza is reported to be on the increase in various cities in England and on the continent. In London it is reported to be raging in very grave form, chiefly of the gastric type. During the week before last there were forty-three deaths returned as from influenza, the largest number reported in any one week for three years past.

Medical Society of the State of New York.—The ninety-second annual meeting of this society will be held at the City Hall, Albany, commencing at 9:15 A.M., January 25, 1898, and continuing in session until 1 P.M., January 27th. Though the society is composed of duly elected permanent members, delegates, and honorary members, provision is made in the constitution for invited guests, and an invitation is extended to all members of county medical societies to attend. On presentation of their names to the committee of arrangements, they will be recommended to the society as invited guests and will have the privilege of taking part in discussions. Reduced fares can be obtained by applying at the railway station on starting for a certificate, which, on indorsement by the secretary of the society and by the special agent of the Trunk Line Association, who will be at the meeting during Tuesday and Wednesday, will entitle to return at one-third fare. The committee on credentials will be at the Kenmore Hotel, Monday evening, January 24th, and members and delegates who arrive then are requested, so far as possible, to register there or otherwise as early as possible after arrival. Invited guests are requested to register also at the place of meeting. The programme, which contains thirty-nine titles, gives promise of a more than usually interesting meeting. Dr. Seneca D. Powell is the president of the society, and Dr. Frederic C. Curtis secretary.

The Baltimore Medical Association and the Baltimore Medical and Surgical Society have reorganized under the name of the Baltimore Medical and Surgical Association.

Water Pollution.—In the suit brought by the city of Cumberland, Md., against the Piedmont (W. Va.) Pulp Works, for polluting the water of the Potomac, the decision was in favor of Cumberland. The drinking-water of Washington is also affected by this pollution.

Obituary Notes.—Dr. Lewis W. Pendleton, of Portland, Me., and Palm Beach, Fla., died at the latter place on January 11th, after a short illness. He was a graduate of the Albany Medical College in 1864.—Dr. C. B. Day, of Glencoe, Minn., killed himself with a revolver on January 13th. No reason is given for the act, but he is said to have been despondent for some time.—Dr. William J. Van Vleck, of Hudson, N. Y., for many years a prominent member of the New York Dental Association and a pioneer in that branch of surgery, died at his home on January 14th. He was in his eightieth year. He leaves a widow and two sons.—Dr. William F. Wiseman, a graduate of Heidelberg, died at Danville on January 14th. His mind had been impaired for some years before his death.

The Bacillus of Pertussis.—The discovery by Dr. Henry Koplik, of this city, of the bacillus of whooping-cough was announced in the Medical Record at the time Dr. Koplik read his paper before the British Medical Association in Montreal. This discovery has been confirmed, according to a European dispatch, by Dr. Czapelewski, a bacteriologist of Cologne. With the exception of the bacillus of influenza, this is said to be the smallest of the bacillus family so far identified. It was present in all cases investigated by Dr. Koplik—sometimes in a state of pure culture. The discovery, it is thought, may lead to newer methods of treatment. Further confirmation will, however, be required before general acceptance can be expected.

Death from Lockjaw after Vaccination.—Suit has just been begun against the city for $50,000 damages for the death of a young girl from lockjaw, supposed to have been induced by impure vaccine used in vaccinating at school by the health board.

Dinner of the Harlem Medical Association.—On the 15th inst. the Harlem Medical Association gave its usual annual dinner at the Harlem Casino. Dr. Philip A. Maleson acted as toastmaster. The respondents were Surgeon-General George M. Sternberg, Drs. S. M. Jacobus, J. E. Janvrin, Thomas H. Manley, and John Shrady.

The Maryland Medical and Chirurgical Faculty will complete the one hundredth year of its existence in 1899, at which time a centennial volume containing the annals of the profession of Maryland will be issued.

Baltimore's Oldest Physician, Dr. Morris Wiener, celebrated his eighty-eighth birthday recently. Dr. Wiener is in active practice.

Cambridge Hospital.—It is possible that a hospital may be built in Cambridge, Md., which is the largest town on the eastern shore of that State.

Dr. Robert T. Wilson has been elected chief surgeon of the Woman's Hospital of Baltimore, to succeed his father, Dr. H. P. C. Wilson.

The Water Supply of Washington.—A resolution providing for the filtration of the water used in the city of Washington was recently introduced into the senate. Senator Hale said that in no part of the United States was there a city whose citizens were so imposed upon and abused as to the water supply as are the citizens of Washington. "We are confronted with bad, foul water," said he, "so filthy, indeed, as to make it dangerous to drink and irksome even to take a bath." Senator Gallinger, the mediæval opponent of all progress in medicine and hygiene, characteristically sought to obstruct the measure. He is unfortunately a member of the District of Columbia committee, and is also, we are told, or was at one time, a physician, and so his utterances in sanitary matters are received by some of his colleagues in the senate with a seriousness which they are far from meriting. He delivered himself of the opinion that the water of the city was not impure or specially hurtful to the consumers, and he opposed the proposal to establish filter-beds because they would cost money.

The New York County Medical Association, at a meeting held January 17th, elected the following: *President*, Dr. George T. Harrison; *Vice-President*, Dr. Frederick H. Wiggin; *Recording Secretary*, Dr. Michael C. O'Brien; *Corresponding and Statistical Secretary*, Dr. Parker Syms; *Treasurer*, Dr. John H. Hinton; *Members of the Executive Committee*, (for four years) Dr. Joseph E. Janvrin, (for one year) Dr. Charles Ellery Denison.

The Conditions of Medical Practice in France.—Dr. Lloyd O. Thompson, of Greenwich, Conn., writes that some time ago, his attention having been called to the restrictions imposed upon foreigners wishing to practise medicine in France, he addressed a letter of inquiry to a friend occupying an official position in France. The answer which he received was as follows: "Physicians and dentists must have a certificate of birth, a diploma of B.A., and their medical or dental diploma legalized by the consul-general of France of the country from which they come. These papers have to be translated into French by a sworn translator, after which they are sent to the minister of public instruction, accompanied by a demand. At the Sorbonne one can generally get a diploma of 'bachelier' (B.A.), on paying expenses amounting to about 160 francs. With this the applicant presents himself before the Faculty of Medicine, and, according to the value of the medical diploma that he has, is accorded twelve or fifteen inscriptions, with dispensation from scholarship; that is to say, laboratory, dissection, hospital work, etc. But last year a law was passed, by which the greatest difficulties are created for physicians from abroad, so that now there are hardly any foreign students in Paris. An honorary diploma has been created for foreigners, which does not give them the right to practise in France. To have that right one must be of French nationality or must have got his B.A. in France. To pass the examinations two years at least are required; the examinations must be passed in French, and in good French certified by professors. Dentists not having a B.A. must have at least equal to the French *brevet supérieur*. With that the demand is addressed to the minister, accompanied by the dental diploma. The successful applicant gets twelve inscriptions at once, with dispensation from scholarship in the dental schools. After that he has to pass three examinations in medicine—two theoretical and one practical. Since this new law has been in effect (about four years) not a single dentist from abroad arriving in France has been able to pass the examinations."

School Instruction in Germany on the Effects of Alcohol.—An effort is being made by temperance agitators in Germany to have introduced into all the primary schools in that country a course of instruction on the baleful effects of alcohol. A memorial from the Berlin Anti-Alcohol League has been presented to the government, calling attention to intoxicating beverages as a common cause, especially, of brain affections. The memorial points out the greater susceptibility of the young and growing undeveloped organism to the influence of alcohol in impairing physical strength and in predisposing to alcoholic addiction. The government is therefore petitioned to order, in the interests of the German people, instruction in the alcohol question in all governmental schools.

Irregular Medical Practice in Massachusetts.—A bill regulating medical practice is to be introduced into the Massachusetts legislature, by means of which it is hoped to drive out of the State all fraudulent and incompetent practitioners of medicine, especially Christian scientists. The followers of this belief will, it is said, make a hard fight against the bill.

To Prevent Errors in Compounding.—Dr. E. F. McIntosh, of New Haven, referring to some recent mistakes by drug clerks, writes that he has known of fatal accidents due to the carelessness of the physician in writing an adult dose when the prescription was intended for a child or an infant, and the druggist, not knowing the age of the patient, naturally compounded the prescription exactly as it was written. To obviate such a fatal error Dr. McIntosh has printed on all his prescription blanks:

"This is designed for { an adult, / a child, / an infant."

He draws his pen through two of these lines, the remaining one indicating the age of the patient for whom the prescription is intended.

The Costliness of Errors in Drug Compounding.—A jury in the supreme court in Brooklyn has given a woman in that city a verdict of $5,000 in her suit against a druggist for the loss of her husband, who was killed by a dose of oxalic acid put up by mistake in the druggist's store for Epsom salts.

Turpentine in Tuberculosis.—Dr. J. S. Prettyman writes that, in the formula for a turpentine mixture published in a recent issue, the amount of acacia emulsion should be four ounces, instead of four drachms, as printed.

Dr. Grigoriĭ Antonovitch Zakharĭin, of Moscow, professor of clinical therapeutics at the university, and formerly physician to Tsar Alexander III., died on January 5th. Dr. Zakharĭin, though long and favorably known for his scientific attainments and laughed at for his eccentricities in Russia, was first introduced to the western world through the report of a quarrel he had with Leyden, of Berlin, at the time of the late Tsar's final illness. According to the generally accepted report, he was worsted in his dispute with the "foreign interloper," and started to leave Livadia, but was restrained by the Tsar's chief of staff, who virtually placed him under arrest. When the Tsar died Zakharĭin's house in Moscow was attacked by a mob, and rumor had it that he was to be banished from the country. The new Tsar, however, presented the physician with a jewelled snuff-box, on which was an enamelled portrait of his father, thus intimating that he did not agree with those who decried Dr. Zakharĭin's professional ability. Thi saction of the new ruler brought about a revulsion of feeing in the physician's favor, and when he delivered his first lecture in Moscow after his return from Livadia he was received enthusiastically by the students.

The Passing of Tuberculin.—The announcement is made that the manufacture of Koch's T. R., the new style of tuberculin, has been abandoned. It will be remembered that the publication of Koch's paper describing his wonderful extract was made on April 1st.

A Quarantine Law in Iowa.—A medical law recently enacted in Iowa provides that when a family is quarantined for one of the infectious diseases, such as diphtheria or measles, the head of the family or bread winner may attend to his regular business, but must change his clothing immediately before going out and returning home; he must also wash his hands, face, head, and beard with a two and one-half per-cent. solution of carbolic acid immediately before leaving his home; he must not act as nurse or live in the same room with the sick person; and is not allowed to attend church or any place where other persons are assembled. This privilege does not apply, however, to school teachers or others whose occupation brings them in intimate contact with children.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending January 15, 1898. January 8th.—Medical Director B. H. Kidder detached from duty with the medical examining board, Washington, January 21st, and ordered home on waiting-orders. Medical Director B. H. Kidder retired January 23d. January 13th.—Passed Assistant Surgeon A. W. Dunbar detached from the *Vermont* and ordered to the *Nashville*, January 15th; on arrival of the *Nashville* on the European station ordered to the *San Francisco*.

The Plague continues to increase in Bombay. On January 4th and 5th there were 142 new cases and 105 deaths in that city. There is a general exodus of the population and an absolute suspension of business is feared unless the fresh panic can be allayed. An interesting report has recently been issued upon the epidemic of plague in Damaun, Portuguese India, and the effect of preventive inoculation there. The facts upon which this report (abstracted in *The Lancet* of December 18th) is based were collected by Professor Koch and Professor Gaffky, with M. Haffkine and Surgeon-Major Lyons, the president of the bubonic plague research committee; and their informants were Col. J. P. Villar, the governor; Mr. Judge, the assistant collector; Shet Sorabjee, the head of the Parsee community; and six medical officers. The daily mortality from the beginning of March to May 19, 1897, was 30 per diem—a grand total of 2,325 deaths. Of this number 2,093 were authenticated by means of a house-to-house inquiry among the particular families in which they had taken place. Among the Parsee community, numbering 306 persons, 276 were inoculated twice and 1 was inoculated once. Of these 1 only died, a woman who had been inoculated only once and that, as was afterward seen, subsequently to infection by plague. Thus the total mortality among the inoculated Parsees was only 1 in 277—a percentage of 0.36. Among the 29 uninoculated there were 4 deaths—a mortality of 13.8 per cent. Among Shet Sorabjee's servants and laborers, numbering 200 in all, all were inoculated but one. That one was attacked on May 16th and died on May 19th, while among the inoculated one person, a child aged four years, was attacked and died. Of other members of the population of Damaun between March 26th and the end of May among 6,033 uninoculated there were 1,482 deaths, or 24.6 per cent., while among 2,197 inoculated there were 36 deaths, or 1.6 per cent. If the inoculated had died in the same ratio as the uninoculated, the number of deaths among them would have been 332 instead of 36. Owing to the extreme demand for lymph, the later inoculations were much weaker than those done at the commencement of the epidemic and the difference in favor of the stronger lymph was most marked, for out of 1,924 inoculated with the strong lymph there were 70 cases, 3.6 per cent., with 22 deaths, 1.1 per cent.; case mortality, 31.4 per cent. Out of 270 treated with weak lymph there were 21 cases, 7.8 per cent., with 14 deaths, 5.2 per cent.; case mortality, 66.7 per cent. Figures such as these show the extreme value of the preventive treatment, taken as they are from the course of a most virulent epidemic and during the highest stage of the outbreak.

The Maryland State Medical Examining Board is considering the matter of selecting three of its members from the faculties of the medical schools. This, however, has been opposed by the State Medical Society and the matter is still undecided. The State legislature may be called on to amend the medical-practice act.

Rush Medical College.—At a meeting, December 29th, the trustees of the University of Chicago, in response to a petition from the trustees of Rush Medical College, voted to enter into affiliation with that college. The date proposed for the consummation of the relationship is June 1, 1898, but it is specifically stipulated that the affiliation shall be dependent upon three conditions. The first condition is that the board of trustees of Rush Medical College shall be reorganized. At the present time a great majority of the trustees are physicians, who are at the same time members of the faculty. The new trustees will be representative business men of Chicago, who have no pecuniary interest in the income of the college. The second condition provides that the requirements for admission to the college shall gradually be increased, until, in the autumn of 1902, only those who have completed the freshman and sophomore years of regular college work shall be admitted. The third condition provides that affiliation shall not take place until the debt of Rush Medical College, amounting to $71,000, has been paid. The proposed affiliation will give to the university a general supervision of the educational policy of the institution, but the trustees of Rush Medical College will continue to be an entirely separate corporation, and the University of Chicago assumes no financial responsibility in connection with Rush Medical College.

Society Reports.

NEW YORK MEDICO-SURGICAL SOCIETY.

Stated Meeting, January 3, 1898.

JOHN BLAKE WHITE, M.D., PRESIDENT.

The Management of Patients before and after Laparotomy.—DR. FREDERICK HOLME WIGGIN read a paper with this title (see page 115).

The Laparotomist Should be a Wise Physician.—DR. GEORGE T. HARRISON expressed great satisfaction at the stress laid in the paper upon the importance of the preparation and preliminary observation of the patient. The laparotomist should be not only a skilled and experienced surgeon, but a wise physician. In these days in which the Trendelenburg posture is so much employed it is more than ever important that the bowels should have been previously emptied and collapsed, so as to be up under the diaphragm, out of harm's way. It was also desirable to administer the night before operation some intestinal antiseptic, such as powders of salicylate of bismuth. He objected to the giving of food shortly before the administration of the anæsthetic; the last food given should be the night before. He had seen the method tried of giving brandy just before the operation, to brace up the patient, but, according to his observations, it acted the opposite way. As a rule, if the laparotomist could get along with morphine, it was better to withhold it, but no routine method should be followed—indeed, a combination of morphine, atropine, and strychnine constituted one of the best heart tonics known. In some very restless and nervous patients the administration of morphine was unquestionably beneficial. In cases in which many intestinal adhesions had been separated at the time of the operation he thought it important to clear out the bowels on the third day. If within thirty-six hours after any operation the patient had not been able to pass gas naturally, the greatest relief was afforded by an enema of hot water and glycerin. To Lawson Tait belonged the credit of having called attention to the fact that when certain symptoms developed catharsis was of great value. The cases in which Tait recommended this treatment were those in which on the second or third day the patient became restless, the abdomen distended, and no gas could be passed. After a while vomiting began, then the vomited matters became darker, and with this the pulse became weak and rapid and the countenance anxious. When these symptoms first developed, catharsis was of great benefit. Another excellent plan was lavage of the stomach, together with the administration of enemata of glycerin and hot water. In this condition of intestinal paresis septic material readily passed through the intestinal wall into the peritoneal cavity. As a rule, the clearing out of the bowel under such circumstances brought permanent relief, yet he had met with a number of cases in which even this treatment, promptly and efficiently carried out, failed to avert a fatal termination.

The Trendelenburg Posture Unnecessary and Dangerous.—DR. A. PALMER DUDLEY spoke briefly of his own individual experience. In his opinion four days should be long enough for proper preparation of the patient, providing the surgeon was already familiar with the constitution of the patient. A week was too long to keep a patient in dreary expectation. He did not like calomel, because it nauseated a great many persons, and therefore he substituted three compound cathartic pills. He preferred to operate in the morning, if possible, and did not allow food later than the previous night. No matter what was introduced into the stomach, it would cause a flow of gastric juice, which would produce vomiting and disturbance. If strychnine were given freely to the patient for two or three days prior to the operation, the patient would be thoroughly stimulated beforehand. He did not make the incision through the recti muscles, because he did not know at the beginning how large an incision would be required. He never used the Trendelenburg posture, believing it to be unnecessary and dangerous, owing to the extra pressure put upon the heart and lungs, and on the cerebral circulation. He washed out the abdomen, but always dried it instead of leaving any saline solution in the general cavity.

Feeds Patient with Seidlitz Powders.—As soon as the patient came out of the ether he began the administration of the salines in hot water. Not long ago at the Harlem Hospital he gave sixteen Seidlitz powders in twenty-four hours, without the slightest disturbance or rise of temperature. His object in doing this was to give something for the patient to vomit, should vomiting occur, and also because he did not want the gut to remain long in one position if there were intestinal surfaces liable to form adhesions. He did not believe in intestinal paresis—indeed, he had never seen this complete paralysis as described by many observers. This free use of the salines did not cause excessive purgation, but it did do a very important service, *i.e.*, kept the contents of the small intestine moving. After twenty-four hours, if the bowels had not moved he placed the patient in the Sims position, and gave an enema consisting of two ounces each of glycerin and sweet oil and two drachms of turpentine. He not only did not restrict the patient's movements but rather insisted upon their moving about and changing their position in the bed frequently. He preferred half-grain doses of codeine to the use of morphine in those few cases in which such a drug was indicated, and he attributed his low death rate—4.5 per cent.—to the very simple treatment which he was in the habit of adopting.

DR. H. LILIENTHAL suggested that it was well to make as many preparations as possible for an operation without the patient knowing that it was to take place, in this way doing away with much nervous strain. In fat patients he believed sewing the skin was the cause of a great deal of trouble. By using chromic gut or even silkworm gut through both fasciæ, preferably in two layers, granulation might be allowed to close the wound. He advocated giving an enema of whiskey and salt solution before resorting to intravenous saline infusion. It was usual for a chill to follow the intravenous injection of saline solution, although he did not know the cause of this. It was next to impossible to generalize regarding the after-treatment of cases of abdominal section, because of the great variety presented in this field.

Hint as to Control of Vomiting.—When chloroform anæsthesia had been used it was very useful to pour vinegar on the mask as soon as the patient began to come out of the chloroform. This would do much to control the vomiting. The washing out of the stomach was very grateful to the patient. He wished to state that he differed absolutely from Dr. Dudley regarding the Trendelenburg position. He could not conceive of this posture being the direct cause of death, and it was an exceedingly valuable surgical resource.

Long Preparation Influences Patient Unfavorably.—Dr. E. E. TULL, speaking of the effect of environment, said that he had observed at one time in a hospital where it had been the practice to keep the patients for a long time under observation before operating that these were not in so good condition as when the preparatory treatment had not been so

prolonged. He had done some very severe though successful operations in wretched tenement houses.

Stitch Abscesses.—While he was an interne in the Woman's Hospital it had been the rule to look at the dressings on the fourth or fifth day, and at that time stitch abscesses were not infrequent. Several of the surgeons sewed up all the layers, while others sewed up only certain layers, so that he had had an opportunity of comparing the two methods. He believed that the dressings should not be changed under ordinary circumstances for eight days, so as not to interfere with the healing process. At the end of this time the dressings should be carefully removed, but the sutures allowed to remain two or three days longer. He greatly preferred using one layer of sutures as being much less likely to cause strangulation of the tissues. As to the significance of the pulse rate, the speaker said that he had seen a pulse of 140 to 160 in a woman who before operation had had a normal pulse, yet in this instance the rapid pulse seemed to have been entirely the result of nervous excitement. Morphine in small doses he had found exceedingly useful in certain cases in which vomiting was very troublesome.

A Caution about the Trendelenburg Position.—He found the Trendelenburg posture an exceedingly valuable adjunct, although it was the part of prudence to make sure that all blood-vessels were secured after the patient had been returned to the horizontal position. He did not like the use of calomel, because it caused a great deal of nausea. The rectal tube would be found exceedingly useful in cases in which there was much accumulation of gas.

Hospitals Not a Necessity for Abdominal Surgery.—Dr. S. C. Gordon, of Portland, Me., said that he agreed fully with Dr. Wiggin when he said that the day of hospitals had gone by as a necessity in abdominal surgery, and he no longer believed that it was necessary to operate in an atmosphere of steam and carbolic acid, or tear up all the carpets and furnishings. He did not believe that patients should know long beforehand that they were to be operated upon. He did not like calomel to begin with, although it was useful afterward.

Give Strychnine and Water Freely before Operation.—He favored strongly the continuous administration of strychnine for days beforehand—one-thirtieth of a grain three times a day. If the time of preparation were short, he would give it every three hours. After the operation he also insisted upon the systematic use of strychnine. He had very little faith in the subcutaneous or intravenous injection of saline solutions. He did not like morphine, and was sure that it had been responsible for a great deal of intestinal paresis and for the masking of many important symptoms. He favored giving food for the last time at night, and operating the following morning. It was well not only to allow, but to insist upon, the patient drinking a great deal of water before and even up to the time of the operation. If these patients were thoroughly saturated with water, they would suffer afterward very much less from thirst.

An Ether Mask Preferred.—For the administration of ether he much preferred a piece of Turkish towelling (one thickness) stretched over a wire frame. He did not like any apparatus requiring the patient to breathe the same vapor again and again.

Sutures Often Removed too Early.—In suturing, he carried silkworm gut through all the tissues, the sutures being about one inch apart. If the abdominal walls were quite thick, he stitched the fascia only with catgut. He tied the silkworm-gut sutures moderately tight, and did not remove the dressings or disturb them for from one to two weeks. At the end of this time he removed every other suture and left the others another week, unless there was some special irritation. He believed that Warren, in his "Surgery," had demonstrated some years ago that it required at least three weeks to get good solid union. Dr. Gordon said he felt that in the past he had removed the sutures too early—certainly his later experience with the other method just described had given much better results. He did not restrict his patients to teaspoonful doses of water, but allowed them to take it freely, and if they vomited they had something in the stomach to vomit. In his experience hemorrhage after abdominal section had been uniformly fatal, and unless there was some reaction reopening the abdomen was, to say the least, very unsatisfactory. Stitch abscesses, he believed, were always due to infection, and not simply the result of drawing a suture too tight.

Rule about Cathartics.—His rule about cathartics was to withhold them for two or three days in ordinary cases, and from his own experience he was inclined to doubt very much the efficacy of intestinal peristalsis in preventing intestinal adhesions. If the temperature rose to 100.5° or 101° F., it was his habit to begin the use of cathartics. If there was much vomiting he used the tablet triturates of calomel for a few doses and then administered one teaspoonful of a saturated solution of sulphate of magnesium at intervals of one to three hours. This was the best saline, in his opinion. He very rarely used the Trendelenburg position, unless some complication arose.

No More Preparation for Laparotomy than for Perineorrhaphy.—Dr. W. M. Polk said, regarding the preparatory treatment, that, assuming that the patient was in proper condition for an operation, he favored making as little preparation as possible—in other words, he made no more preparation for a laparotomy than for a perineorrhaphy. Inquiry into the condition of the assimilative and excretory processes was probably the most important preliminary step. He made use of the Trendelenburg posture whenever possible, and of the saline solutions before the patient was in an extremely dangerous condition. It had not been his experience that patients were very much hurt by knowing beforehand that they were to be operated upon—indeed, it could not be avoided in hospital practice. He saw no reason why a person about to be subjected to laparotomy should not go to a theatre the night before, if so minded.

Etherization the Source of Much Mischief.—Dr. Polk said that most of the trouble experienced after these operations was, in his opinion, not due to the laparotomy, but to the etherization. He was satisfied that much of the intestinal paresis met with was due to this cause, and probably the result would not be materially different even with the new anæsthetic method of Schleich. If morphine were to be used, it should be used with the distinct understanding that it was an evil, though perhaps the lesser of two evils. Most of the patients felt better if purged not later than forty-eight to seventy-two hours after operation, or rather, after etherization. It seemed to him at least possible that intestinal peristalsis might prevent the formation of adhesions, and hence when many raw surfaces had been left he would be disposed to avail himself of the possible benefits of catharsis.

Give Solid Food Early.—Regarding the diet, he would say that he thought the sooner these patients were placed back on solid food the better; and even after the second day tea and coffee and things of that kind that appealed to the patient's palate should be allowed.

Estimate the Daily Quantity of Urea.—Dr. Egbert H. Grandin said that all seemed to be agreed regarding the broad principles underlying the after-treatment of these cases. In his opinion, the preparatory treatment had more to do with the state of the

kidneys than with that of the intestinal canal, although he would not underestimate the importance of having the great sewer of the body clean, empty, and healthy. The urine should be examined quantitatively, particularly as regards the quantity of urea excreted. He was not afraid of letting the patient know that an operation was to be performed. In the after-treatment we must distinguish between the simple and the complicated cases. In those cases in which the peritoneal cavity was unaffected and there were no adhesions, it was of but little importance whether or not the bowels were moved promptly; but when there had been many adhesions or pus had escaped into the peritoneal cavity, it seemed to him better that the bowels should be moved as soon as the nausea following the anæsthesia had disappeared. He favored the use of a saturated solution of Epsom salts, and it would be retained better by the stomach if given hot. It seemed to him a positive advantage to allow the patient nutritious food quite early, and solid food in ordinary cases after the bowels had been freely moved.

Uses Strychnine and Saline Enemata Freely.—For stimulation he gave as much as one-sixteenth grain of strychnine every two hours, and allowed hot saline solution to run in and out of the bowel continuously for two or three hours. It certainly stimulated the action of the kidneys, relieved thirst, and tended to diminish shock.

Opium Only when Clearly Indicated. — He had been brought up in the opium school, but had lived long enough to repent it. Then, following Tait and others, he had gone to the other extreme. At the present time, he was adopting what seemed to him a more rational course, namely, to use opium when the indications seemed plain. For example, in neurotic patients, suffering intensely, he did not believe that a hypodermic injection of morphine would do harm, but would, on the contrary, do much good. He used codeine by preference in as large doses as four grains by the rectum. One-half grain of codeine by the mouth seemed to him an exceedingly small dose.

The Patient Selects the Cathartic.—Dr. Robert A. Murray thought it was better to use calomel at the beginning of the week of preparation, for not only were there very few people who were not nauseated, but there were very few who were not exceedingly depressed by its use. He did not, however, lay much stress upon the cathartic used, and it was his habit to allow the patient to select his or her customary cathartic.

Cathartics and Intestinal Adhesions.—The good effect of cathartics in preventing intestinal adhesions might be explained by its favoring the absorption of exudation, and so allowing no soil for sepsis. It was almost always the rule, in cases of intestinal paresis, that sepsis was also present. He believed much of the nausea and vomiting after operations was due to overnarcosis, and that a too tightly drawn suture, by lowering the powers of resistance of the tissues, might cause necrosis and so allow of infection.

Uses Opium in Intestinal Surgery.—Dr. Frederick Kammerer thought that almost every case could be prepared for laparotomy in one or two days. In all his intestinal work he put the patient on opium for eight or ten days, and in these cases he had never seen a bad result from confining the bowels so long. Of a very large number of intraperitoneal abscesses with no adhesions he had never lost one, and he had adopted this same plan of treatment in almost all of them. His object was to avoid breaking the tender adhesions and disseminating septic material through the peritoneal cavity.

Turpentine Enemata for Intestinal Distention.—Dr. Parker Syms believed that the use of opium in surgery was very rarely indicated. It was chiefly of value as a stimulant after shock, particularly abdominal shock. In the majority of his clean laparotomies he had not found it necessary to give any cathartic; a low rectal enema was often all that was required. For dislodging gas from the intestine, he knew of nothing more valuable than the introduction of turpentine into the bowel.

Dr. Wiggin closed the discussion. He said he had never experienced any trouble in using calomel to empty the bowel, and had found also that it exerted a beneficial action on the kidneys. He had never observed any harm from the use of the Trendelenburg posture. The use of small quantities of ether in a closed inhaler certainly caused little excitement at the time, and very little digestive disturbance afterward.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 22, 1897.

Warren Coleman, M.D., Vice-President, in the Chair.

Malformation of the Heart.—Dr. Harlow Brooks presented a heart that had been removed post mortem from a married woman, thirty-nine years of age. She had been a heavy drinker, and gave a history of rheumatism, but not of syphilis. Her last illness began last August, with shortness of breath on going up and down stairs, and œdema of the lower extremities toward evening. At the time of entering the hospital there was general œdema, and she complained of palpitation of the heart. She died two days later, the temperature during her stay having ranged between 97° and 100° F. It was noted at the autopsy that the face was much congested and the ankles were œdematous. The pleural cavity contained one and one-half litres of very clear serous fluid. The pericardial sac was greatly dilated, and occupied the entire anterior and left mediastinal spaces. The heart was enormously enlarged and its chambers were contracted. The muscular walls were comparatively thin, and the muscle itself was soft and somewhat œdematous. The cavities contained a considerable quantity of post-mortem clot. The conus arteriosus was dilated and its walls showed diffuse areas of arterial sclerosis. The coronary arteries were the seat of extensive atheromatous disease. At the base of the conus a foramen was found, measuring one and one-half centimetres. It was bisected by a column of tissue, one millimetre in diameter. The edges were smooth and rounded, and it led into a sac which bulged into the right auricle. This sac was spherical, and both the external and internal walls were smooth and free from calcareous deposit. It measured three centimetres in diameter. The mitral segments were markedly retracted. There were similar lesions in the right side of the heart, which was decidedly dilated. The heart weighed twenty-eight ounces. The liver was congested and of the nutmeg type, and the kidneys were also congested. So far, no microscopical preparations had been made of the wall of the sac. He had not seen or heard of a similar specimen, but was inclined to look upon the condition as congenital. Possibly it was an aneurism.

Dr. Rowland G. Freeman said that the specimen did not admit of any very positive expression of opinion, yet it seemed to him to present the appearance of an aneurism, in spite of the fact that there was no evidence of disease of the surrounding wall.

Dr. Brooks said that the existence of the small band of tissue had led him to the conclusion that the formation was probably a congenital one.

The society then adjourned.

The Cyclist is often found to have cyclic albuminuria.

Progress of Medical Science.

Operative Treatment of Cancer of the Rectum.—Dr. Desforges-Mereil (*Journal des Praticiens*) describes an operative procedure which he considers eminently fitting for this affection. After having successively passed in review the coccygeal, sacral, parasacral, vaginal, abdominal, perineal, and abdominosacral ways, the author concludes that it is best to return to the perineal method of Lisfranc, modified by himself as well as by other modern surgeons. This method is the most convenient and the surest, as it permits the entire lesion to be laid open, and allows us to see its connections with other neighboring organs. From a clinical standpoint the author establishes, according to the anatomical divisions of the rectum, two classes of rectal cancers—the recto-pelvic cancer extending from the third sacral vertebra (superior limit of the rectum) to the levator ani, and the recto-perineal cancer, extending from the levator to the anal orifice. Every cancer situated above the third sacral vertebra the author considers as a tumor of the sigmoid flexure and not a cancer of the rectum. The true cancer of the rectum should be treated by the sacral method or by prerectal extirpation and suture of the two ends by a special method of the author which he calls the recto-pelvian. The recto-perineal cancer would justify the amputation of the rectum according to Lisfranc's method, and suture of the rectum in the levator ani (the process of the writer). In inoperable cases an iliac anus will be found expedient, made by special process of the author. These processes of extirpation have been tried on the cadaver and on the dog, and have given the author excellent functional results.

The Radical Cure of Hernia.—Dr. Lucas Championnière (*Lyon Médicale*, August 29, 1897) publishes the results that he has obtained in the treatment of hernia during sixteen years. He has operated upon 650 inguinal hernias, 501 of which were in males and 49 in females; 46 crural hernias, of which 13 were in males and 33 in females; umbilical hernias, 22, all in females; epigastric hernias, 14, all in males; hernias elsewhere, 12—in males 2, in females 10. The relapses have been 23 in number. Those completely cured could exercise freely without artificial support. The relapses occurred in hernias of the large intestine, in obese or aged patients, who had either emphysema or cough from other conditions. Sudden emaciations were a notable cause of relapse. The mortality from this operation is small. Dr. Championnière in one series of two hundred and sixty-five cases did not have a single death. Statistics of young subjects gave a mortality of only 0.2 per cent., or one death to every five hundred operated upon. The fundamental elements in regard to operation that the author emphasizes are destruction of all accessible omentum and of the peritoneum in the whole extent of the sac, and reconstruction of the wall, making it as thick as possible.

Serum Treatment of Leprosy.—Dr. Carasquilla (*Gazette Médicale de Liége*, October 7, 1897) announced to the Academy of Medicine that he had discovered a new method of treating leprosy by injection of an antileprous serum. He declared that this treatment ameliorated the state of the patient and sometimes even brought about a complete cure. Unfortunately for the victims of this disease the predictions of Dr. Carasquilla have not been realized, and the cures announced have been only apparent. The error was entirely excusable, for leprosy is an affection which advances by successive stages which are often followed by prolonged periods of improvement, sometimes so marked as to seem like cures. If the treatment is given during this stage, one might attribute the cessation of the acute symptoms to the remedy employed, but the same improvement would have been noted had there been no intervention. The antileprous serum of Dr. Carasquilla is prepared by injecting serum from the blood of a leprous subject into horses. It does not seem to possess any really beneficial action upon a subject of leprosy. This result has been shown when a patient submitted for a long time to its action, without any improvement except that which is ordinarily noted in the interval between acute attacks. This discovery has been announced prematurely, but there is no need to lose hope of finding an efficacious serum. However, it is requisite to seek it by other ways and means than those employed by Dr. Carasquilla.

Chronic Gastric Ulcer.—Dr. Nauwerk (*Gazette Médicale de Liége*, October 7, 1897) gives a description of the stomach of a woman, sixty years of age, who died from peritoneal perforation; there were present a number of ulcers, two of which had been the direct cause of death. Ulceration and gastritis had constituted a combined process; in this case one could speak of the condition as one of chronic ulcerous gastritis. The ulcer and erosion could not be separated, as there was between the two lesions only a difference in degree; both were phenomena of the same disease. Microscopical study enabled him to note that the mucous membrane of the stomach was affected by numerous necroses which had an approximate depth of one millimetre. As to the origin of these necroses, they could be attributed neither to anæmia, blood infarction, nor bacteria. They seemed rather to have been made by corrosive process, aided by chronic inflammation of the mucous membrane. It is fitting to note that the patient in question was a very stout woman who often eat voraciously of many indigestible dishes. She suffered with her stomach for a number of years and often had eructations. In 1894, hæmatemesis occurred and it was at that time that a diagnosis of ulcer of the stomach was made. The author thinks it ought to be remarked that the most of these cases diagnosticated as chronic catarrh of the stomach might be classed as chronic ulcerous gastritis.

The Pathological Physiology of Thromboses or Blood Coagulations.—Dr. Cornil (*Gazette des Hôpitaux*, August 28, 1897) gives the following *résumé* of his paper: 1. The organization of intravascular blood clot is made at the expense of cellular elements of the internal lining of the vessel, namely, the endothelial cells of the veins and arteries. The fibrous network of the blood clot serves as a support for the development for these elements. 2. The phenomena of organization are very rapid; they commence from the first day, by modifications in the endothelial cells. The capillaries appear about the third or fourth day and connective tissue about the ninth or tenth. 3. The extent and degree of traumatism that the vessels have sustained have a certain influence on the extent and rapidity of the organization. Infection of the blood clot, on the contrary, delays these phenomena. 4. The phenomena of organization are everywhere the same wherever the seat of blood coagulation may be, whether a vessel, the heart, the lungs, or cellular tissue. According to the location the agent of organization is vascular, cardiac, pulmonary, endothelial cell, or better the cell of connective tissue from which the others are derived.

A Study on Immunity.—Dr. Roger (*Gazette des Hôpitaux*, August 28, 1897), in a paper on the rôle

and importance of immunity and on the modifications of different humors noted in acquired immunity, gives the following conclusions: "After our study we can better understand the causes of immunity, and can penetrate into the mechanism put into operation by the human economy for the resistance of infections. It has been easy to demonstrate that physical conditions are not capable of explaining the phenomena that we have studied. The intervention of chemical and vital causes is essential. But the changes produced in the constitution of the humors and of the tissues are not primitive; they depend on the nutritive activity of the cells. The cells exercise their protective rôle in two ways: 1. By secreting soluble substances, some of which diminish the activity of the microbe; others increase the resistance of the organism against toxic substances. 2. By uniting, destroying, and digesting the elements formed. What is the part played by each of these modes of defence? If we admit an actual modification of the humors by animal vaccines, we naturally attribute the initial action to them. From the time that a microbe comes into the organism which has been rendered immune, it is immediately plunged into liquid endowed with a certain antiseptic power. Then the weakest microbes will be destroyed; those having more resistance will present signs of degeneration; some, however, will develop and increase. But it is the general biological law that the properties of cells are dependent upon the medium in which they are developed; consequently the bacilli acquire different characteristics. Now experiment shows that in the serum of vaccines the microbes are often deprived of their virulence, and research will probably establish the fact that the same thing occurs in the living organism; hence the bacteria become incapable of secreting substances which interfere with diapedesis. The cells can hasten over the invaded point, and, though attacked by parasites that are weakened by the humors, they can easily resist the invasion. Without the intervention of phagocytosis the microbes could develop as they do in serums outside the body, and the disease, instead of being retarded in the first stage and attenuated in its manifestations, would have fully developed; without the action of bactericidal humors the cells would have been incapable of eliminating the microbes. In a word, with vaccinated animals phagocytosis finishes the work commenced by the humors. The two processes are equally indispensable in order that the organism may triumph over the disease. Without doubt this theory, like all others, is destined to be greatly modified, but it seems to be supported by numerous and exact facts. The latter point to the final conclusion that if the means at the disposal of the organism for combating infection are numerous, they may all be referred to the same source; immunity is the property of the cell."

Epididymectomy either Partial or Total in Primary Tuberculosis of the Testicle.—Dr. T. Dimetresco (*La Médecine Moderne*, October 2, 1897) says that epididymectomy is an operation of recent date; it was in 1880 that Bardenhauer did the first systematic operation of this kind, and since that time, while instances have multiplied, but few as yet have been published. Before discussing the expediency of the operation, Dr. Dimetresco says that there is a primary tuberculosis of the testicle with integrity of the other organs. It can remain localized for a long time in the epididymis before reaching the body of the testicle and other portions of the genito-urinary apparatus. We should not wait until the body of the testicle, the vas deferens, and the prostate become involved before operating, for by operating in good time not only will the extension of the tuberculosis be hindered, but a cure may be effected which will last for some time or even be permanent. Epididymectomy is the only treatment that gives any guarantee of success. It should be partial if the vas deferens is healthy and if there is only a small nucleus limited to the extremity or to the head of the epididymis; it should be total when the tuberculous nodules are disseminated or are of considerable volume. One should make a resection of the epididymis also if a small portion of the testicle is involved; removing, layer by layer, all the diseased parts until healthy testicular tissue is found. Epididymectomy does not lead to atrophy of the testicle; this comes on only in instances in which the vessels of the cord have been compressed in the ligation of the vas deferens or wounded during operation. As long as the testicle continues to secrete, even if the patients remain sterile, they do not remain impotent. In five cases of partial epididymectomy seen again after four years, three years, one year, and three months respectively after operation, there were four completely cured, with the genital functions completely preserved and the general health excellent; the fifth still had a small mass adherent to the skin and the testicle. Of ten patients who had undergone epididymectomy, with or without resection of the vas deferens, for unilateral tuberculous epididymitis, nine have since been seen, two and seven years after operation; six were completely cured without testicular atrophy and their genital power was preserved; three others, after three years, two years, and one month, had relapse with fistulas. Two patients having double tuberculous epididymitis were operated upon and seen again, the one after four years, the other after a few months; the first was completely cured, the second had a relapse limited to one side. In the observations of Bardenhauer, reaching the number of eleven cases, with bilateral epididymitis, the results of resection have also been for the most part excellent.

Hemorrhage from the Normal Kidney.—Dr. G. Kemperer (*Deutsche med. Wochenschrift*, 1897, Nos. 9 and 10) says that it is shown by clinical observation and deduction that hemorrhages may occur from an otherwise normal kidney as a result of or under nervous influences (as in hæmoptysis or hæmatemesis); also that experimentally irritation of the nerves in rabbits has several times resulted in the production of hemorrhage from a healthy kidney. There are many records of cases in which on account of hemorrhage a kidney has been removed by the surgeon, and the organ found not to be diseased. The author explains these cases as being the result of a vaso-constrictor paralysis. Six cases that came under his own observation he classifies as follows: 1. Two cases, hemorrhages of but short duration resulting from overexertion (bicycle exercise); prognosis very good. 2. Two cases of prolonged hæmaturia in hæmophilic subjects; the diagnosis was based on the family history and the fact that the patient had previous to this had other hemorrhages. In such cases all operative interference, even cystoscopy, is contraindicated. 3. Two cases of prolonged angio-neurotic hæmaturia; thus diagnosticated because the bloody urine was a simple mixture of blood and urine, and did not show the presence of any other pathological elements, while palpation showed no enlargement of the kidney. Treatment consists of rest in bed, milk diet, suggestion, the application of hydrotherapy, and perhaps electricity.

Etiology of Progressive Paresis.—Krafft-Ebing (*Centralblatt für Nervenheilkunde und Psychiatrie*, October, 1897) states that this heretofore almost unknown disease has within the present century become a dread among mankind. The increase has been a steady one, representing in 1838 to 1840, 12.6 per cent., 1867

to 1871, 18 per cent., and at the present time 23 to 25 per cent. of all cases of insanity. It is much more common in men than in women, and now occurs at an earlier age than was formerly the rule. Formerly occurring between the thirty-sixth and forty-sixth years of life, it is now also observed in adolescence. It has also become more frequent among women: previously in the proportion of 8 to 1, at present it is 5 to 1. Syphilis stands foremost as the etiological factor in paretic dementia, and is very probably the sole cause of the disease (as in tabes). In favor of this view is the following experiment: Eight paretic subjects, all far advanced and hopeless cases, were inoculated in various places on the body with the secretion from a fresh chancre, and were then carefully observed for one hundred and eighty days. In none of them was there any syphilitic reaction. From this the author concludes that in all these patients there existed latent syphilis sufficient to render them immune to fresh infection. Moreover, a primary lesion (chancre) has never been observed in a paretic subject, although cohabitation is possible in the early stage of the disease. Further points in favor of the luetic origin are: 1. Nearly all the juvenile cases of dementia show other manifestations of congenital syphilis. 2. It is much more common in cities than in country districts. 3. It is quite common among officers of low station, and rare among higher officials. 4. It is rare among women of rank. 5. In localities where syphilis is rare, paresis is rare. 6. Dementia usually manifests itself in from five to fifteen years after infection with lues, and this is an explanation of the occurrence of cases in youth. Considering the great mental strain that this generation is subjected to in the "struggle for existence," it may be said that paretic dementia is a combined result of "civilization and syphilization."

Digital Compression of the Prostate.—Dr. A. Guépin (*Gazette des Hôpitaux*, August 28, 1897) concludes his article on this subject as follows: Digital compression of the prostate, properly performed at the exact time that it is indicated, and used in connection with other measures familiar to all, aids in allaying prostatic inflammation and relieving urinary troubles, and in lessening liability to infection. Compression is especially useful in senile hypertrophy when the walls of the glands are not too sclerotic, as then the cure of all morbid symptoms from which the patient suffers is still possible; it also shortens the time of treatment. In many glandular affections of the prostate and vesicles compression is one of the most efficient agents at our disposal for favoring a return of the glands to their normal state. The technique of the procedure is simple. After the necessary precautions in rectal examination of the prostate have been taken, the index finger should explore the organ, and, dilated glands which give the sensation of small cysts in the rectum being recognized, compression of these points is authorized when they have a certain softness and yield under pressure. If there is the least resistance or the slightest pain is experienced by the patient, the finger should be withdrawn. In this digital compression the greatest prudence should be exercised, for it may provoke, in inexperienced hands, an aggravation of the trouble. One séance is not ordinarily sufficient to reduce all the glandular dilatation, but the compression should be repeated at intervals during treatment. It should be discontinued when the prostate has diminished in volume, has acquired a uniform consistence, and when compression no longer provokes a discharge of any liquid.

Consanguinity.—Dr. Deneffe (*Journal d'Accouchements*, August 22, 1897) says that the bad results of consanguinous marriages have been observed since ancient times. In breeding animals the principles of consanguinity have enabled us to emphasize characteristics that would otherwise be lost: it has permitted the creation of certain races, but this consanguinity has no value unless it is governed by those competent to choose their subjects. Without this selection consanguinity in animals gives as bad results as in man. With animals as with men it emphasizes the defects and vices. The selection so easy with animals is impossible with man. In our civilization, in these times of alcoholism and neuroses, there are not many families without defects, and heredity also complicates consanguinity. Experience shows us that consanguinous subjects, who seem exempt from all defects, reproduce in their offspring the defects of distant ancestors. It is difficult to get a thorough knowledge of the individuals themselves, and impossible to know much of their ancestors. There are villages in which consanguinous marriages are frequent, and where the race is nevertheless fine and vigorous. Dr. Deneffe gives many absolutely contradictory facts. He refers to the Protestant communities living during the sixteenth century in the midst of Catholics, and forced by this circumstance to tolerate consanguinous marriages. These marriages gave worse results than crossed marriages. The author considers that consanguinous marriages are always dangerous.

Auclair's Tuberculin Experiments.—Dr. J. Auclair writes in *La Médecine Moderne*, October 2, 1897, that to prepare the tuberculin, Koch reduced the cultures of bouillon to one-tenth by boiling. He has attempted to find out the immunizing power of the nine-tenths which evaporated. These products of distillation of bouillon, in which have been cultivated the tubercle bacilli, are toxic to the healthy guinea-pig. The toxicity is more and more marked as one applies a greater degree of distillation to the bouillon. In tuberculous guinea-pigs these products hasten the evolution of the disease, and for the time being cause an elevation of temperature: the action approaches that of the tuberculin of Koch. In preventative injections it does not seem to produce any immunity. There are two kinds of bacillary forms obtained by placing ether with human tubercle bacilli and heating to 100° F., for five or ten minutes. One of these forms consists of light bacilli which float on the surface of the ether for a time. These rarely killed guinea-pigs even when large doses were administered, but produced a marked local reaction, characterized especially by the formation of an abscess, then an ulcer. These lesions never became generalized. The other class, on the contrary, consists of a heavy form of bacilli which fall to the bottom of the ether and, when injected in large doses, cause death in the animals without the formation of local lesions, but with a general dissemination of the bacilli in the organs. Experiments made with ethereal extract of human tubercle bacilli tend to prove the slight toxicity of this product: it did not cause death until a long time after inoculation and the lesions noted at the autopsy were limited to congestion of the lungs. At the point of inoculation a tumefaction is produced, which is hard at first and suppurates later. In tuberculous guinea-pigs the ethereal extract does not appear to have any effect on the evolution of the disease, and preventive injections do not produce any immunity against human tuberculosis. From these and analogous experiments made with chloroform extract, ethero-chloroform extract, ammoniacal extract, and alcoholo-camphorated extract, Dr. Auclair concludes that the substances derived from the bacillus of Koch do not possess any immediate toxicity for healthy animals. The slow action of these products, compared with that of those which are toxic, is in harmony with

clinical facts, which make tuberculosis essentially a slow disease. When it kills rapidly it is rather by spreading or by the location of the lesions than by the toxicity of the products elaborated by the bacilli. When the toxicity does not manifest itself in an immediate manner, the bacilli do not necessarily make less poisonous substances, but, acting at a distance from the point of inoculation, the evolution of the disease is slow; others are active at the same point where they are deposited, and produce abscesses and centres of necrosis. In these results clinical and experimental work are in accord. The fever and decline of phthisis are engendered by the rapid increase of the bacilli of Koch and the diffusion of the poisons that they secrete. It is, moreover, difficult to deny the importance of secondary infections. With the tuberculous, two causes concur to aggravate the disease—intoxication and the infection which is constantly going on. With each movement a new quantity of toxin is added to that already secreted and is scattered through the organism, and thus the source of poison is indefinitely extended by the rapid increase of the bacilli. Clinical observation as well as research seems to indicate that tuberculosis is a disease which vaccinates. Dr. Auclair has little faith in vaccination against tuberculosis by the products drawn from the bacillus of Koch. In his experience these products have shown a toxicity against which it is necessary to be on one's guard; if it is slow in its action, it is also slow in its elimination and consequently reaches points distant from the lesion. Our knowledge of the necrosing action of the dead bacilli and their resistance to causes of destruction indicate that in an individual affected with tuberculosis it does not suffice, in order to effect a cure, to prevent the increase of the bacilli and to kill those inclosed in the organs; but it is necessary also to ward off accidents that the dead bacilli effect, as they are charged with products capable of starting up suppuration and necrosis. In order to bring about a sure and lasting cure of tuberculosis, it is necessary, according to Auclair, first, to conquer infection; second, to cause an immunity which will last long enough to admit of the bacilli being destroyed or ejected; and lastly, to prevent the evil effects that follow in the train of the poisons secreted by the bacilli.

Albuminuria in Dyspeptics.—Dr. Robin (*Journal d'Accouchements*, August 22, 1897) says that to-day every one admits the existence of functional albuminuria; that is to say, albuminuria existing without accompanying lesions. With functional albuminuria it is necessary to include albuminurias of hepatic origin, of nervous origin, of alimentary and dyspeptic origin; it is of the latter variety that Dr. Robin writes. Albuminuria which manifests itself in the course of dyspepsia presents peculiar characteristics which permit its diagnosis not only from Bright's disease but also from other functional albuminurias. The patients in whom this variety of albuminuria is encountered are affected with gastric hyperæsthesia, variable distention of the stomach, increase in the volume of the liver, constipation, and fæcal accumulation in the bowel. They complain of a sensation of weakness and fatigue; they are thin and have vertigo, but never present œdema. If we examine their urine we find sometimes an irregular albuminuria and sometimes a continuous and permanent albuminuria. This undergoes considerable variation according to the diet of the patient. The albumin is composed of serum without globulin. As to the urine, it never contains tubular casts, but a certain quantity of indican and crystals of oxalate of calcium are found. The state of nutrition and the organic and respiratory changes will furnish other signs which will aid in differentiating dyspeptic albuminuria from other varieties. In those affected with this form of albuminuria one finds an increase of the coefficient of oxidation of nitrogen and an exaggeration of organic demineralization and a diminution of pulmonary interchange. Dyspeptic albuminuria has been attributed by most authors to a reabsorption of toxins evolved in the digestive tract. The author does not agree with this idea, but, on the contrary, thinks that this affection is engendered by the passage into the urine of nutrient albumin which has not undergone modifications in the stomach which fit it for assimilation, and thus it acts in a manner as a foreign substance. Alimentary albuminuria can be cured when it is properly treated in the beginning; that is, when it exists only in an intermittent form. When it becomes continuous it is cured only in from thirty to thirty-five per cent. of instances. The treatment is extremely simple and ought to be based, during the first stage at least, on the state of the digestive tract. Diet forms the prime element of treatment and varies with each case; if there is less albumin with animal diet than with vegetable, animal diet should be prescribed, and *vice versa*. The diet should be mixed if it is found that there is less albumin under such conditions. It is almost useless to call attention to the fact that it is nearly always necessary to have recourse to a milk diet. This should be suspended if the patient begins to grow thin.

Prevention of Vomiting after Anæsthesia.—Capt. E. B. Frick, assistant surgeon, Presidio, San Francisco, Cal., claims that the inhalation of the acetum aromaticum, N. F., is a reliable preventive of vomiting after anæsthesia. His opinion is founded on personal observation. He states that in many of the cases he was present as operator or assistant, while in the others the facts were gathered from the records of a private hospital in San Francisco. The aromatic vinegar was administered by inhalation from a saturated handkerchief as soon as the anæsthetic was discontinued, and was kept up for an hour or longer if called for by the occurrence or persistence of nausea or more active gastric disturbance.

Formaldehyde Generator.—Surgeon Walter Reed, curator of the Army Medical Museum, made some experiments recently with a Hollister's formaldehyde generator. The results of these experiments showed that while occasionally an unprotected cover slip spread with streptococcus pyogenes aureus and bacillus diphtheriæ may be destroyed after twenty-three and one-half hours' exposure, the amount of formaldehyde gas furnished by this generator is, as a rule, quite insufficient for the disinfection of either infected clothing or surfaces even when unprotected.

The Diagnostic Value of the Widal Reaction in Typhoid.—S. Gerlóczy (*Pester medicinisch-chirurgische Presse*, 1897, No. 23), from an examination of the blood serum of eighty-six persons, thirty-seven of whom were undoubtedly affected with typhoid, the others being cases of pneumonia, scarlet fever, measles, diphtheria, variola, varicella, and pertussis, arrives at the following conclusions: 1. The reaction is always present in a clinically outspoken case of typhoid; on the other hand, the presence of the reaction is not a positive indication that typhoid exists, since it may occur in other diseases. 2. During the progress of the disease or in recent cases along with agglutination there is a complete and permanent cessation of motility, while in cases that have long since run their course the cessation of motility accompanying agglutination is only apparently complete, since in these cases the bacilli very often regain their activity after a few hours. 3. In other diseases the blood serum does not behave in the same manner; but in those cases in

which agglutination does occur the bacilli recover their motility after a few hours. 4. The specimen should therefore be examined again after twenty-four or twenty-eight hours to determine whether the bacilli are again active. 5. Absence of agglutination excludes the diagnosis of typhoid. Complete and permanent agglutination does not with certainty signify typhoid, for this reaction may take place in cases that have already run their course.

The Action of Quinine Sulphate in Strengthening Labor Pains.—While quinine sulphate has little or no power for inducing labor pains, Schwab (*La Méd. Mod.*, 1897, No. 3) is positive that after uterine contractions have once begun the administration of quinine causes them to become rapid and energetic. He obtained excellent results from its use in all cases of prolonged labor due to uterine inertia. While quinine strengthens the labor pains, it does not tend to induce abortion. Unlike ergot, it causes intermittent and not tetanic contractions, and may therefore be prescribed without danger during the second stage of labor. Its action begins in about one-half hour; the drug is therefore best given in two doses of eight grains each, within a period of ten minutes. Quinine is indicated if, after rupture of the membranes, labor is unnecessarily prolonged on account of uterine inertia, the mother is exhausted, and there is danger of the child becoming asphyxiated. While quinine has a tendency to produce post-partum hemorrhage, this is easily controlled by massage of the uterus.

Chlorosis.—Dr. Molle (*La Loire Méd.*, November 15, 1897) calls attention to a chlorosis similar to that seen in young girls, which affects boys at about the time of puberty. The symptomatology includes general weakness, nervous disturbances, interference with digestion, palpitation, etc. A constant objective sign is the presence of a venous souffle exclusively limited to the femorals. These femoral souffles accompany or supplant those in the jugulars pointed out by other authors. In twenty young girls affected with chlorosis, examined during the past three years, the author has never been able to discover the presence of this femoral souffle. The discovery of this sign should make the diagnosis positive. Medical treatment and general hygienic care are called for during this critical period through which the subjects are passing.

Locomotor Ataxia.—The *Gazette Médicale de Liege*, August 26, 1897, gives a *résumé* of Dr. Grasset's interesting paper on this subject, read at Moscow. He considers first the nature of tabes dorsalis. As there is no specific treatment, therapeutical indications can be drawn only from a knowledge of the nosological nature of this disease. Tabes is well defined on the one hand by the symptoms of its evolution (the clinical history); on the other by its lesions (anatomical history). This anatomo-clinical syndrome forms part of a more general disease—multiple disseminated sclerosis. For, first, in tabes taken alone there are often sparse scattered sclerotic lesions; second, with tabes there are other nervous anatomo-clinical syndromes which correspond to other scattered centres of sclerosis of the nervous system; third, with tabes we as frequently find, associated in the same subject, various scleroses of other organs besides the nervous system. The etiology of tabes is as complex as that of multiple disseminated sclerosis. Syphilis is the most frequent cause, but this is not the only etiological element even in cases in which it is found. Arthritis, different intoxications, the neuropathic disposition, either hereditary or acquired, as well as other causes, play their part. There are numerous other etiological elements which co-operate either to produce the disease or to determine its localization on the sensitive medulla. As to its curability, tabes is curable. Facts prove clearly that it may be clinically cured even though the lesion remains. Again, tabes may also present remissions and partial retrogressions of sufficient duration to be highly desirable for the patient. Even in less favorable cases we may obtain periods of relief. Locomotor ataxia is not implacably progressive. In spite of the pathological anatomy and the discouraging results in definite sclerosis of the medulla, there is room for study of the treatment of tabes and a discussion of our resources. We can class under three heads the therapeutical effects to be sought in tabes. We may seek, first, to cure or to ameliorate the anatomical state of the medulla: second, to re-establish the functions of the diseased medulla; third, to allay the painful symptoms. The means proposed to fulfil these indications are classed in three groups: first, those means directed to the etiological factors (agents modifying the causes of tabes); second, means directed toward the anatomical factors (agents modifying the lesions of tabes); third, means directed to symptomatic factors (agents modifying the symptoms of tabes). In the etiological treatment of tabes it is necessary to discuss the antisyphilitic treatment, the anti-arthritic treatment, and various other etiological treatments. First, antisyphilitic treatment is not harmful in tabes. Often it is beneficial, and in exceptional cases it cures. One ought to find out whether previous syphilis is certain, probable, or only possible in the patient. The first treatment should be mixed, and should last about three months; later, if found necessary to return to this same treatment, it is advisable to regulate the treatment according to the effects produced upon the patient when under previous treatment. The employment of chlorinated and sulphuretted waters is also indicated. Second, the anti-arthritic treatment embraces the alkalies, iodides in weak doses, arsenic, and a particular diet and hygiene, together with certain mineral waters. Third, the indications drawn from other etiological factors are incorporated in the etiological treatment of the neuropathic state in general. The therapeutical agents directed to the lesions of tabes find their indications in the sclerotic nature of the lesions or in their medullary localization. First, for sclerosis we employ preparations of the iodides, especially tincture of iodine; the salts of silver, if there is an intolerance for the iodides; rye ergot in the acute or subacute stages; and antisclerotic diet, which is very important. Second, the means of local revulsion directed more especially to the medulla (in the acute and subacute stages) are certain electro-therapeutical measures, elongation of the nerves, but little used at present, and different methods of elongating the medulla. Among these latter means, suspension should be retained as a useful measure in essentially chronic phases of the disease. It is directed to an actual sclerosis after the first stages, or to a cicatrix rather than to the disease in its active and progressive stages. The symptomatic treatment may be arranged in five groups: First, for the shooting pains and visceral neuralgia, all sedatives are indicated—opium, antipyrin, etc. (Avoid injections of morphine as far as possible.) For the gastric crises, employ oxalate of cerium. The study of the chemistry of the stomach will furnish other useful indications. To this group belong a number of external means—revulsive, chloroform, cold water, electricity, sedatives, mineral waters. Second, for the deficient muscular power one may use Sequardian medication and nerve transfusion, which could be better replaced to-day by injections of artificial serum and glycero-phosphates. To this group belong internal tonics, general and special; also massage, hydrotherapy, electricity, and mineral waters. Third, for the ataxia re-education of the muscles, according to the method of Fraenkel, is a recent and useful proc-

ess; this is the re-education of the brain or the development by cerebral action of a medullary compensation compatible with the persistence of the lesion. This method should be employed aside from the time of acute or subacute attacks, when the sight, the intellectual functions, and the muscular power are sufficiently preserved. Fourth, without speaking of the simulated hysteria of tabes, one ought to mention that neurotic phenomena occupy in the symptomatology of tabes a more important place than is generally given them. The first and principal means of combating these symptoms are suggestion. To the same group belong certain electrical applications, hydrotherapy, and certain mineral waters. Fifth, vesico-rectal, ocular, trophic, circulatory affections, and bulbar crises have their special indications in individual cases.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PRINCE'S FUND—DR. MURPHY'S REPORT—SIR E. FRANKLAND'S REPORT—THE TYPHOID EPIDEMICS—CLIFTON AND MILK—THE MEDICO-CHIRURGICAL DEBATE—DANGER OF IMPORTED MILK—NEWPORT HOSPITAL DIFFICULTY—RECENT HONORS—RECENT DEATHS.

London, December 31, 1897.

The distribution of the Prince of Wales' fund has begun. University College Hospital has been awarded £2,581 5*s.*, of which £1,181 5*s.* is a special donation in honor of the Queen's diamond jubilee, and the other £1,000 is a subscription. This award will relieve for the moment the pressing straits of this hospital, which, as I lately informed you, was closing fifty beds and running a risk of disqualifying the school. A pressing appeal for funds to avert this is being made to the public.

Other hospitals are receiving awards on a similar basis. It is desired by the council to assist in reopening closed wards and making all beds available for the suffering poor. The great hospitals will thus receive most of the money, though some crumbs may fall to the small special hospitals.

Dr. Shirley Murphy, the medical officer of health for the county of London, in his new report to the council, gives a voluminous statement on the sanitary condition of the metropolis.

Curiously, both the birth rate and marriages have been for a long time slightly declining, which, considering the enormous population and the tendency to overcrowding in certain areas, is, *pace* some political economists, not altogether unsatisfactory. More certainly, however, the fall in the death rate is a cause for congratulation to all parties. There was an improvement in this noticeable as long ago as 1871, since which on only two occasions—1875 and 1878—has the rate equalled the average of the last half-century. There has been a striking and continuous fall in the rate of small-pox, typhoid, and whooping-cough. There were more fatal cases of whooping-cough last year, but that is the only exception to the continuous fall for the last twelve years. Dr. Murphy finds the fatality of diphtheria and scarlet fever has been greatest at the beginning and end of the year, and least in September and October. Insufficiency of hospital accommodation is reported from eleven districts. It is reported that all the infants who died in Fulham from diarrhœa were hand fed. Dr. Murphy condemns a number of tenements which have been converted to such use from old-fashioned houses. The conditions of life in them, he says, are bad and the rents high. He would like to see a new street made east of Regent Street, which could go far to displace speculators in unwholesome tenements.

Sir Edward Frankland's report to the County Council states that for some unexplained reason nearly all the water companies were last summer suddenly unable to perform their work of bacterial purification. Of the five companies which draw from the Thames, four were smitten with a microbial epidemic in June, and the other was affected early in July. Of the two companies drawing from the Lee one escaped, but every one of the filter beds belonging to the others yielded an enormous excess of microbes. No explanation of this remarkable invasion can be given. Its general occurrence seems to point to some condition affecting the rivers, as accident or carelessness would not be likely simultaneously to affect all the supplies except one.

Maidstone is not even yet out of the wood, a new case or two occurring on most days, and the total has now reached 1,897, while 158 remain under treatment. The question of remuneration for the doctors is looming up, and it is to be hoped the authorities will not forget the devotion that has been displayed. The government inquiry is expected to begin about the 20th of January.

At Clifton the outbreak of typhoid was quickly traced to infected milk, and so suppressed. Dr. Davies, the medical officer of health, made a statement of the case at the adjourned meeting of the Medico-Chirurgical Society, which was regarded as most satisfactory and complete. Mr. Tivy, a local practitioner, attended and took exception to the conclusion, and thought the drains were to blame. No one attached much importance to his remarks, but he has since written to the journals in support of his opinion. I hear that all the local practitioners except Mr. Tivy are convinced that the conclusions of Dr. Davies are irresistible. He traced 93.7 per cent. of the cases directly to one source of milk supply, and he says, in reply to Mr. Tivy, that "it seems inconceivable to any rational mind that sewer gas forced indiscriminately into some eight thousand houses, containing over forty-seven thousand people, should attack with remarkable precision only those who obtained directly or indirectly a particular milk, and should select so persistently those who consumed it raw."

In conjunction with the danger from milk, some of the newspapers have lately been agitating the unfairness of permitting foreign milk to be imported. For two years or more foreigners have been sending us milk, and the trade is increasing. Now we insist on our own dairies being brought under the control of the sanitary service, and the proprietors have to incur large expenses in consequence. But we have and can have no such control in other countries, and a recent consular report shows that, even where precautions are taken in other countries for their own consumers, there is no supervision of exported milk. I leave the question of the fairness of this free trade to others, but it certainly seems illogical to take such costly care as to our own products and none at all as to what other countries send us.

The Newport infirmary difficulty is not yet at an end. The board has intimated to the ophthalmic surgeon to whom it gave notice of dismissal that it will enter into consultation with him as to the future when he has made a public apology for his refusal to see the patients he considered improper subjects for charity. Mr. Ensor will not apologize, as he feels he has done only his duty. It seems to be taken for granted that he technically broke the rules, but perhaps a judge would hold that these rules are binding on the directors as much as on the officers, and as they had not inquired into the cases reported they were not acting on their own rules. Not that I would recommend a lawsuit. It would be better for the whole staff to ap-

peal to the subscribers to hold a meeting and discuss the merits of the questions involved. The most important of these for the good of the hospital is whether the committee should have the power arbitrarily to dismiss the honorary staff.

In future the examinations for the army medical staff and the Indian service are to be identical and held simultaneously. Candidates may enter their names for both services, and, if successful, choose according to their places on the list, subject to being qualified under the regulations special to each service. The director-general of the army medical department, Surgeon-Major-General Jameson, has been appointed honorary surgeon to the Queen, in the vacancy occasioned by the death of Sir William Mackinnon.

A companionship of the Bath has been conferred on Surgeon-Lieutenant-Colonel and Commandant Norton. You may not recognize the gentleman under the cloak of his cumbersome military title, which is an apt illustration of the "compound titles" now given to doctors by the "military advisers." Mr. Norton is no other than the surgeon of St. Mary's Hospital, in which undress you will know him. He has taken the greatest interest in the volunteer movement from the beginning, and his oppressively compound titles are derived from his steady work in that department of the national forces.

A number of jubilee medals have been given to several sorts and conditions of men, among whom medical officers in the services have come in for a small share. These honors have not been conferred in a batch, but ever since the medals were ready have been distributed one or two at a time, so that in most weeks there has been an announcement of one or more. The last recipient is Sir Joseph Fayrer, Bart., M.D., F.R.S.

Dr. William Wadham died on Tuesday. He was for many years dean of St. George's Hospital, and exercised an excellent influence over the students, sympathizing thoroughly with their play as well as their work. He was himself fond of athletics, a good oarsman and horseman, as well as a sure shot. He was born in 1823, took M.D., St. Andrew, 1847, was elected on the staff of the hospital in 1862, and remained until 1887, when he became consulting physician and gradually withdrew from practice, though he retained his interest in his profession and hospital, where he delivered an interesting address last year. Dr. Wadham belonged to the past generation of physicians, and relied a good deal on the clinical instinct, which he possessed in an unusual degree. He did not write much, but he polished his lectures, of which the style was very attractive, and his clinical instructions were much valued by careful and hard-working students.

Joseph John Fox, M.R.C.S., etc., died on the 15th inst. He was born in 1821, and belonged to the Society of Friends. His family was connected with the late Mr. Forster and with Tragellas, the biblical scholar. His own hobby was mathematics, with which he relieved the cares of practice and solaced himself in the retirement forced upon him by Ménière's disease many years ago. Three of his sons are in practice.

Dr. G. H. Evans, one of the oldest practitioners in Lancashire, died on the 11th inst. He was born in 1833, and qualified in 1858. He was ill about three weeks, and received a public testimonial only a few days before his death.

Deputy Surgeon-General Houstan died on Christmas Day, aged sixty-five. He retired in 1886.

Surgeon-Lieutenant-Colonel Wilson was found dead on a couch, after a fire which occurred in his house on the 13th inst. Death was evidently due to suffocation from the smoke. He retired in 1894.

OUR BERLIN LETTER.

(From our Special Correspondent.)

PHYSICIANS AND THE SCHOOLS—PHYSICIANS AND THE LAWS—ROENTGEN PHOTOGRAPHS—NO MORE HEADACHES—A NEW SUSPENSORY SUBSTITUTE—MOVEMENT THERAPY FOR ATAXIA AND OTHER NERVOUS DISEASES.

Berlin, December 24, 1897.

The instruction at one of the local academies had recently to be suspended for several weeks, because about three-fourths of the scholars were taken ill with measles contracted at the institution. No one at the commencement of the epidemic saw to it that the gymnasium was closed; the well was covered, as the Germans say, after the child had fallen into it. This event emphasized the necessity for school physicians. Many prominent laymen and physicians of Berlin have taken up the matter and several meetings have been held. It is demanded that each school have assigned to it a school physician, to have charge of the general hygiene of the building and be watchful over the health of the scholars; to see to the proper heating, ventilation, cleanliness, and, if necessary, disinfection of the building; to order the closing of the school when the heat becomes excessive, and in times of epidemics; furthermore to examine new scholars — in short, the school physician should protect the scholars against the dangers of the school life. The authorities appear very favorably inclined to this proposition, and it is believed that the reform will be instituted.

There is a movement on foot in Berlin to provide free courses to physicians, in which they shall be instructed in all the laws bearing upon the profession and its practice. As it is now, there exists a sad ignorance on these matters among the younger men fresh from the university. According to the plan proposed a physician shall receive clear explanations of the laws concerning accidents, insurance, judiciary functions, etc., and it is hoped thus to protect him from the injury and annoyance to which he is so often exposed.

Dr. Berend announced at a recent medical meeting that the falling out of the hair, observed so often after employment of the *x*-rays, is only temporary, and that therefore the rays are of no value for the removal of hair growing in abnormal places. Drs. Levy-Dorn and Lassar reported cases of severe dermatitis following transillumination. According to Levy-Dorn this annoyance can be avoided by having the source of light quite distant from the body. A Roentgen photograph of a syphilitic gumma of the humerus of a child was shown by Dr. Heller; between the periosteum and bone was a dark spot representing the solution of the calcium salts. Dr. Treital located by means of the *x*-rays the position of a set of false teeth swallowed, and then extracted them with a pair of curved forceps. He claimed that either sounding or œsophagoscopy would have been a very dangerous procedure.

At the Berliner medicinische Gesellschaft an apparatus for the treatment of migraine was demonstrated by Dr. Ewer. With it a constant percussion of a measurable degree of force may be applied to the painful area. This idea of alleviating pain through vibrations is an old one: Hippocrates speaks of it, and the Romans had apparatuses constructed for this purpose. Ewer's apparatus, which bears the name of "the tremulor," has a wheel inclined forward and moving on a rotatory axis. Attached to this wheel is a rubber knob, which, when the wheel is in motion, comes in contact with the painful spot.

Gerson's improvement on the suspensory is well worth mention. It consists simply of an elastic bandage hemmed with a soft border, and covered with a

non-irritating zinc and gutta-percha plaster. The annoyance of the thigh and pelvic straps is entirely avoided. The scrotum is to be shaved and then the testicle may be held by the elastic bandage as high as may be desired. Gerson employed the bandage with good results in about one hundred cases.

Dr. Frank at the Verein für innere Medicin showed two patients whom he relieved from trigeminal neuralgia by means of a new method. Both suffered most excruciating pains, and the usual internal remedies, as arsenic, etc., as well as excision of the supra-orbital and infra-orbital nerves had no effect whatsoever. But the pains vanished permanently after one or two injections of a one to one and a half per cent. solution of hyperosmic acid into the painful areas. Frank therefore counsels the trial of this drug before turning the patient over to the surgeon.

At the same society, Professor Goldscheider read a paper on "Mechanico-Therapy in Diseases of the Nervous System." The method embraces the idea of training the visual sense—the patients being for the most part tabetics—so as to have it take the place of the tactile. Beginning with simple movements, they are gradually taught to make more complicated ones; just as a child is taught first to stand, then to walk and to run. This naturally calls for a good deal of patience and perseverance on the part of the patient, but the physician must aid, and can aid considerably, both by encouragement and by proper massage, electricity, and bandaging of the atonic muscles and joints. Besides tabes this method acts well in chorea, intention tremors, athetosis, writer's cramp, hysterical tremor, muscular rigidity of multiple sclerosis. The speaker mentioned particularly exercise in the bath, which yields such good results in polyneuritis, the support given by the water aiding the motion of the limbs markedly. The results obtained in tabes by means of this movement therapy have thus far been very good.

THE JUDGING OF COMPARATIVE RESULTS IN THE SURGICAL ARENA—"MURDEROUS MORTALITY" VERSUS "FANCY STATISTICS."

To the Editor of the Medical Record.

Sir: In the Medical Record of November 28, 1896, Dr. T. Gaillard Thomas deduced a superior operative effectiveness for the operators at the Woman's Hospital, New York, from the following surgical statistics:

Abdominal Sections in 1894 at	Number of Cases.	Recovered.	Died.	Percentage of Deaths.
Roosevelt Hospital	66	50	16	24.24
New York Hospital	67	52	15	22.37
New York Cancer Hospital	104	86	18	17.30
Mount Sinai Hospital	55	46	9	16.36
Woman's Hospital	153	130	23	15.03

In the Medical Record of January 8, 1898, Mr. Lawson Tait uses the same statistical line of reasoning to deduce that the work of the operators at the Birmingham and Midland Hospital is from three to five times as effective as the best American showing. His figures are:

	Cases.	Percentage of Deaths.
In the "bad year" of 1893	176	5.2
In the "good years" of 1885, 1886, 1887, 1888, 1891, 1892	797	3.5

Mr. Tait does not deduce that this superior effectiveness is because the English operators have from three to five times more individual art than American operators; but because he "discovered early in his career the fallacy of this so-called antiseptic craze."

In other words, he proves by statistics that antisepsis kills the American patients. And this shows the facility with which statistics will prove any side of any question.

Mr. Tait says: "That a removable mortality of more than three times that amount [viz., British mortality of 5.5 per cent.] should be allowed to remain as the minimum to be reached in America, cannot be admitted for a moment."

The present writer, in the *New York Medical Journal* of December 12, 1896, academically and impersonally made the following statement upon the subject of surgical statistics:

"As low mortalities cannot be had from desperate cases, we must seek another standard than statistics to test a surgeon's worth, namely, the character of his cases. The conservative man who operates only on grave cases will have a shorter list and a larger mortality than another who operates on everything coming into his hands. Low mortalities mean many easy cases to help average up—cases that the conservative man would not operate on at all."

It is again maintained, in answer to Mr. Tait, that we can judge the character of a man's cases from his statistics. It is therefore entirely logical to say that the more "murderous" a man's statistics are, the more conscientious and conservative he must be considered, assuming proper training and surroundings. For such a man shirks no desperate case to help his statistics; he never operates unnecessarily to lengthen his list and diminish his percentage of mortality.

Consequently the true deduction from this trans-Atlantic comparison is, not that British operators have greater individual art, not that antisepsis kills so many American patients—but that American operators confine their work to graver cases than the gentlemen whose statistics are more alluring.

That this is more than a logical deduction—that it is a true fact statement—is well known to those who have had opportunity to study the question on both sides of the Atlantic.

Eugene Coleman Savidge, M.D.
66 West Fiftieth Street, New York.

FAMILY IMMUNITY TO WHOOPING-COUGH.

To the Editor of the Medical Record.

Sir: Just now the children of our town are afflicted with almost an epidemic of pertussis. In talking with an old lady the other evening, she made what I consider a remarkable statement. Mrs. P—— is a native of Wales; all her brothers and sisters were born in that country. Her children were born in this country. She says her parents had eleven children, all born alive; some died at different ages during childhood, and seven of them grew to be men and women. Not one of them ever had whooping-cough. Mrs. P—— herself has had twelve children. Seven of these grew to adult age and are living to-day: the others were all born alive and died during childhood. Not one of her children ever had whooping-cough. Several of Mrs. P——'s family have married, and she has numerous grandchildren. She can recall very few cases of pertussis among them, but there have been some cases among the grandchildren.

In view of the usual opinion that everybody must have pertussis, I should be glad to learn whether any other such family is on record—particularly as my informant is a worthy and intelligent woman, a keen observer in sickness, and her statement can be implicitly relied upon.

David Taggart, M.D.
Frackville, Pa.

New Instruments.

MARSHALL'S APPARATUS FOR DISLOCATION OF THE ACROMIAL END OF THE CLAVICLE.

By THOMAS R. MARSHALL, M.D.,

PROFESSOR OF ORAL SURGERY, SPECIAL ANATOMY OF THE HEAD, ET., AND ASSOCIATE PROFESSOR OF GENERAL AND REGIONAL ANATOMY AT THE MEDICAL COLLEGE OF VIRGINIA, RICHMOND, VA.

This apparatus which I have devised, and which is illustrated by the accompanying cuts, suggested itself to the writer while himself undergoing the usual bunglesome and uncomfortable method of treatment for this injury. It has given such entire satisfaction to all who have used it, and the writer has experienced such excellent results from its use, that it is offered to the profession at large, with the hope that it may prove worthy of a trial.

The principle of the apparatus is to apply local and firm pressure over the acromial end of the clavicle, absolutely fixing it, and at the same time supporting its middle third, the scapular spine, and the upper end of the humerus. This it will be found to do if properly adjusted.

The apparatus can be made at home or by a saddler. It is composed of a pad, three-fourths of an inch in thickness, covering well the upper aspect of the shoulder, and extending above from the lateral root of the neck down over the shoulder on to the arm, about four inches below the axillary space; here it is held to the arm by an adjustable strap sewed to its lower border. The upper end is held in position by an adjustable strap, passing around the chest, underneath the opposite axilla, and protected in this region, to prevent irritation, by a round pad of cotton batting inclosed in cloth, through which the strap passes. Local pressure over the acromial end of the clavicle is made by an adjustable strap, two inches wide, which passes around the shoulder, over the acromial end, and underneath the axilla. Here again

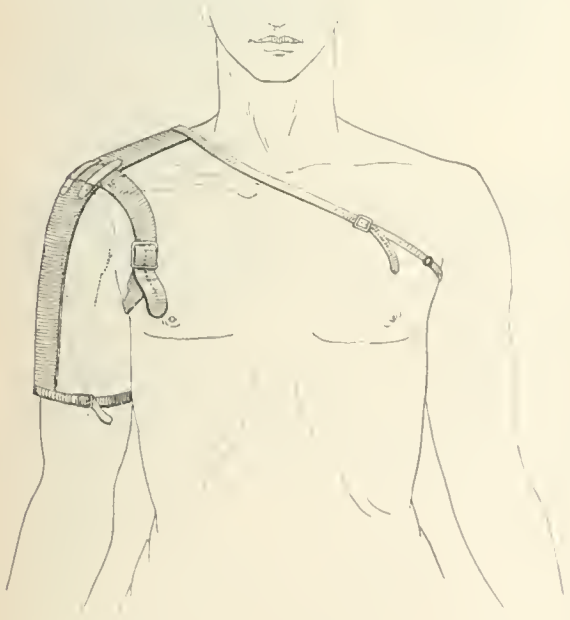

Fig. 1.

this space is protected from irritation by a round pad similar to the other. The strap is held over the acromial end, so that the pressure will be localized, by two transverse strips sewed on either side of the shoulder pad, which also prevents the pad from becoming displaced at its borders.

A very satisfactory apparatus can be made of Canton flannel and cotton batting.

If necessary, immediately after the injury the arm may be held securely to the side by two adjustable

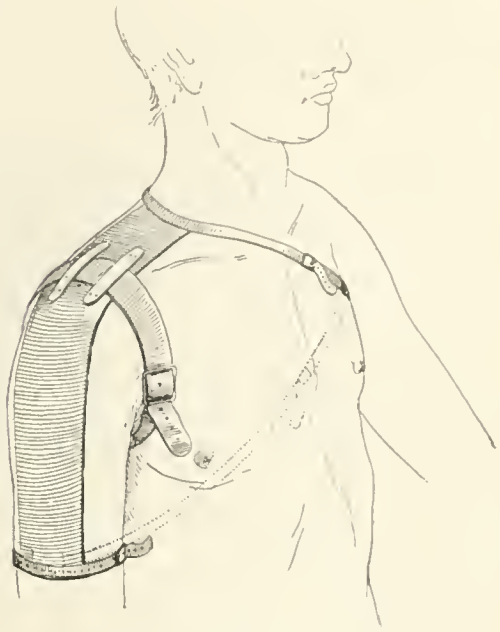

Fig. 2.

straps, extending from the terminus of the pad on the arm to the chest strap as it passes underneath the opposite axilla (Fig. 2). The forearm should then be half flexed and placed in a sling.

218 East Franklin Street.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 15, 1898:

	Cases.	Deaths.
Tuberculosis	170	90
Typhoid fever	12	3
Scarlet fever	232	17
Measles	360	16
Diphtheria	104	15
Laryngeal diphtheria (croup)	14	0
Chicken pox	48	0
Cerebro-spinal meningitis	1	4
Pertussis	1	0
Parotiditis	2	0

Baths.—The kind of bath that is suited to each individual is of great importance. Those who can stand the cold bath should accustom themselves to it as a daily function. The process of training should be commenced by taking a cold sponging, extending only to the neck and shoulders, then gradually increasing until one can get into a cold tub each morning. It should be inaugurated during the summer, as there are then much less shock and discomfort than in cold weather. Salt added to the bath is of undoubted advantage. In the winter the bath should be taken in a well-warmed room, free from draughts. Upon emerging, the body should be vigorously rubbed with a Turkish towel. The exercise and the friction bring the blood to the surface and prevent "taking cold." It is a frequent experience to find that people who were

always chilled by night air, and who took cold on the least exposure, became so hardened by the daily cold bath that they were almost free from such attacks. People usually have the temperature of their baths too high and thereby increase the susceptibility to colds. The Turkish bath is not generally useful, but may be resorted to for special reasons.—Dr. William Ellery Briggs, *Occidental Medical Times*, October, 1897.

Formaldehyde Gas.—At this juncture it might be well to remark upon the effects of formaldehyde gas and its solutions upon textile fabrics, hair, fur, and leather. Experiments were made by subjecting samples of wool, cotton, fur, and leather goods to crucial tests, solutions of various strengths being used, and also a saturated atmosphere of the gas. The results obtained were in every way satisfactory. Of over two hundred and twenty-five different samples of wool, silk, cotton, linen, leather, and hair, employed in the tests, there was no change observed in textile character, even when they were soaked in a strong solution of the gas. Little if any change occurred in the colors of the fabrics, only three of the number showing any change whatsoever—two shades of violet and a light red. The affected colors were a product of coal tar, and were also quickly bleached by the sun.—Dr. J. J. Kinyoun, *Public Health Report*, January 29, 1897.

Sign of Pregnancy.—When the cervix is as hard as the tip of one's nose pregnancy presumably does not exist, but if it is as soft as one's lips the existence of pregnancy is probable.—Goodell.

Nausea of Pregnancy.—One-third of all pregnant women are free from morning nausea during the entire pregnancy, and forty-five per cent. remain free from it during the first three months. If it occurs it presents itself in seventy per cent. of the women in the first month of pregnancy, seldom in the second, third, or fourth months, and very rarely in the fifth and sixth months; in from nine to ten per cent. it begins in the last three months of gestation.—Giles, *Prov. Med. Jour.*, August, 1893.

To Ascertain the Age of a Fœtus.—For the first six months of intra-uterine life the length at different ages is indicated in centimetres by the square of the numerical figure of the corresponding month.—Delabout.

A Long Constipation for a boy of nine years is that related by Dr. Dranitzion, in which, after thirty days without a passage, twenty-three and one-half pounds of fæces was partly extracted with a spoon and partly spontaneously evacuated.—*Lyon Méd.*, November 21, 1897.

Hair Turning White from Fright.—Dr. Parry, in the *Dublin Medical Press* (1861), gives the following instance of hair turning white from fright. On February 19, 1859, the command of General Franks, operating in the southern part of the kingdom of Oude, had an engagement with a body of rebels. Several of the enemy were taken prisoners. One of them, a Sepoy, was led before the authorities to be questioned. "I then had occasion," said Parry, "to observe in this man the events that I propose to relate. The prisoner for the first time seemed to be conscious of his danger when, deprived of his uniform and completely nude, he saw himself surrounded by soldiers. He then began to tremble violently, terror and despair were depicted on his face, and, though he responded to the questions addressed to him, he seemed actually stupefied by fear. Then, under our very eyes and in the space of scarcely half an hour, his hair, which we had seen was a brilliant black, turned gray uniformly over the whole head."

Syphilis Consecutiva.—The following interesting case is narrated by Dr. G. B. Wilson, passed assistant surgeon in the United States navy. Two apprentice boys, aged seventeen years, were tattooed on the left forearms while visiting an English merchant steamer at Buenos Ayres, on June 7th of last year. A chancre appeared on each arm, and was followed by the usual constitutional symptoms.

Snakes Turned to Good Account.—According to an account in the *Journal d'Hygiene*, rats have become so abundant in Brazil that a domestic snake, the giboya, which has about the circumference of the arm, is sold in the marketplace in Rio Janeiro, to be kept in the house as a protection against rodents. It would seem that the serpent pursues its prey more for the pleasure there is in it than from a sense of hunger, since it is said it rarely eats the rats caught. Similar in its habits and attachments to the domestic cat of our more northern latitudes, the giboya will, it is said, find its way back to the house of its master even if transported to a considerable distance.

Health Reports.—The following statistics concerning yellow fever and small-pox have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended January 15, 1898:

Yellow Fever—United States.

		Cases.	Deaths.
Alabama, Whistler	December 27th to January 4th	2	
Louisiana, New Orleans	January 2d to 8th	1	1

Yellow Fever—Foreign.

Brazil, Rio de Janeiro	December 4th to 11th	1	
Cuba, Cienfuegos	December 27th to January 2d		1
Havana	December 31st to Jan 6th		1
Manzanillo	December 1st to 15th		21
Regla	December 31st to January 6th		2
Santiago de Cuba	December 10th to 25th		2
Jamaica, St. Elizabeth	December 19th to 25th	1	1

Small-Pox—United States.

Alabama, Bessemer	January 6th	42	
Birmingham	January 6th	3	
North Carolina, Wilmington	January 12th	1	

Small-Pox—Foreign.

Bohemia, Prague	December 12th to 18th	14	
Brazil, Rio de Janeiro	December 4th to 11th		3
Canada, Montreal	January 4th to 12th	1	
China, Hong Kong	November 20th to 27th	3	3
Cuba, Cienfuegos	December 27th to January 2d		4
Havana	December 26th to January 1st		3
Netherlands, Rotterdam	December 17th to 31st	1	
Russia, Odessa	December 19th to 25th	9	1
St. Petersburg	December 19th to 25th	9	1

Books Received.

NOTES ON A YELLOW-FEVER PROPHYLACTIC FLUID.

BY CHARLES B. FITZPATRICK, M.D.,

ASSISTANT PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES OF THE HEALTH OFFICER'S DEPARTMENT OF THE STATE OF NEW YORK, ETC.

THE relation of yellow fever to the United States is that of an invading epidemic disease. The successful vigilance of Dr. Alvah H. Doty, health officer of the port of New York, and the New York health officer's department, in the detection and prevention of the entrance of the disease into New York during the past year, does not signify that the danger of invasion by this disease is in any degree less real. The last epidemic in the Southern States vividly illustrates the power of yellow fever to invade and become epidemic. The possibility of the disease becoming located in the United States, where the inhabitants have not had the opportunity to become immune against the disease, forms the greatest danger we have to contend with. The facility with which the disease is spread was strikingly shown during the epidemic at Memphis in 1878. Dr. D. M. Bemiss[1] states that of fifty-five unacclimated physicians who exposed themselves during this epidemic fifty-four suffered attacks of yellow fever.

It is readily understood from the above statements that a method of immunizing the persons exposed to the disease would be a most important factor in the successful management of an epidemic. In other words, a method of vaccinating (immunizing) the people against yellow-fever infection would be of the utmost importance from our standpoint. The successful treatment of the disease when once contracted can probably be attained only when a sufficiently powerful antitoxic serum has been perfected.

The results of Haffkine's inoculation in India with his prophylactic fluid against the plague[2] demonstrate that immunization by means of bacterial fluids as a method of preventing infection deserves scientific research and experiment.

I have undertaken a series of experiments with the object of developing a method of immunization or vaccination against yellow fever. These experiments have to a large extent been to use the pathogenic bacteria found at the autopsies of cases of yellow fever, according to methods closely related to those which have been employed by Robert Koch[3] in the preparation of tuberculin, and by Haffkine in the preparation of his prophylactic fluid against the plague. I have also used with the same object in view a culture of the bacillus icteroides, which was very kindly sent to the New York health officer's department by Dr. Jose Sanarelli, director of the Institute for Experimental Hygiene, Montevideo, Uruguay. The autopsies from which the bacteria were obtained by me were made upon three cases of fatal yellow fever in the Swinburne Island Hospital, New York.

The cultures of the bacteria secured by me at these three autopsies were obtained by inoculating the blood of the heart, spleen, liver, and kidney upon different culture media. The organs were opened under strictly aseptic conditions and the blood was immediately placed in bouillon, on serum, agar, and gelatin. Cultures were made from the contents of the stomach and intestines, but these cultures have not been used for the inoculation experiments, as I have not considered them directly concerned in the cause of death or the specific infection. After eliminating all factors of error, and the bacteria which did not appear to be involved in the cause of death or the specific infection, two bacilli remained, which I have found in the three cases, either in the blood and tissue-exudate obtained from the cut surface of the divided liver, or in the blood contained in the heart. One I have designated provisionally as the bacillus coli concentricus, and the other the bacillus coli icteroides. The bacillus coli concentricus has most of the characteristics of the ordinary bacterium coli commune (Escherich) together with some well-defined differences, notably a well-marked property of growing on agar in round colonies of a concentric formation. It is also especially virulent. The bacillus coli icteroides corresponds very closely to the bacterium coli commune (Escherich). I have been unable to discover any sufficiently marked morphological or cultural differences which would justify me in stating positively that it is a different organism. The bacillus coli icteroides possesses an especial virulence—so much so, that it has seemed to me that it has justified a distinct classification and careful consideration as an etiological agent in yellow fever. Both of these bacilli were isolated in the spring of 1897, prior to the publication of Dr. Sanarelli's study on the bacillus icteroides[4] in the June number of the *Annales de l'Institut Pasteur* of 1897. The presence of the bacillus coli icteroides and the bacillus coli concentricus in pure culture, their virulence and marked lesions and symptoms have caused me to regard them as directly concerned in yellow-fever infection and its fatal termination. The further study of these bacilli I have here omitted, and proceed to demonstrate their use in the preparation of a yellow-fever prophylactic fluid. I have also used the culture of the bacillus icteroides sent to me by Dr. Jose Sanarelli. The bacillus icteroides (Sanarelli) was employed to make a prophylactic fluid in the same manner as were the bacillus coli concentricus and the bacillus coli icteroides. The admirable researches of Sanarelli and his wonderful experiments upon man have caused me to consider his bacillus as a possible agent of infection and death in yellow fever, and to use it in some of my experiments. These three bacilli have appeared to me to be better adapted to my purpose than the bacilli described by Sternberg.[5]

The experiments leading up to the preparation of a prophylactic fluid were as follows:

(*a*) Experiments with the inoculation of pure cultures.

(*b*) Experiments with cultures which had been exposed to heat and partially destroyed or weakened.

(*c*) Experiments with cultures which had been grown for four days, then killed by exposure to heat, and further disintegrated.

(*d*) Experiments with the inoculation of pure cultures.

A dog was selected which weighed forty-five pounds, and kept under observation for fifteen days. During this period his temperature varied from 100.8° to 101.8° F. This dog was judged to be healthy and adapted for experimental purposes. The details of the inoculation, etc., are minutely explained in my articles on the preparation of the antitoxins of diphtheria and of the plague.[6] On the 10th of May, 1897, this dog received a subcutaneous inoculation of ten cubic centimetres of the bacillus coli concentricus, which had been grown for fifteen days in bouillon at 37° C. He was inoculated at 4 P.M., at which time his temperature was 100.8° F. At 9 P.M. on the same day his temperature was 104.2 F. The dog was very sick and stupid, was unable to stand, and would not eat. He vomited the stomach contents and some blood. Blood was also passed by the intestines. The dog appeared to get worse and looked as if he would die. In the evening he was still very stupid and weak, but his temperature fell to 103.2° F. During the course of the next five days the temperature gradually by falling about one degree each day reached normal and the dog appeared well again. On May 15th, he was again inoculated with eight and one-half cubic centimetres of a culture of the bacillus coli concentricus, which had been grown in bouillon at 37° C. for four days. The dog reacted after the inoculation with a temperature of 104.6° F. and much prostration. On the 23d of May his temperature had again reached normal. He was allowed to rest for about one month. On June 23, 1897, he received another inoculation of ten cubic centimetres of the bacillus coli concentricus, and reacted with a temperature of 105.6° F., but with very little prostration. In five days his temperature was normal and the dog was apparently in full health. The next inoculation was on the 28th of June, and consisted of the same as the preceding. The reaction this time was 102.4° F. and no prostration, but a disinclination to eat for one day. After an interval of two weeks the following experiment was made. It was ascertained that twenty cubic centimetres of a bouillon culture of the bacillus coli concentricus, which had been grown in bouillon at 37° C. for four days, was a surely fatal dose when injected subcutaneously into a dog weighing forty-five pounds. The dog, which had been treated as above described, received this inoculation, and after a period of sickness lasting five days became perfectly well. This period of sickness was characterized by a rise of temperature to 102.6° F., loss of appetite, and some weakness. A second dog of the same weight was inoculated at the same time with the same amount and in the same manner. The only difference between this control dog and the other was that the control dog had not received any previous inoculations. This control dog died in twenty-four hours after receiving the inoculation. The conclusion to be drawn from this experiment is that previous treatment by a series of inoculations or vaccinations confers such an immunity upon a dog that he is enabled to bear a fatal dose without injury. I made a similar experiment with the bacillus coli icteroides and obtained similar results.

Having the object in view of developing a method of immunization or vaccination which could be safely used upon man, I next proceeded to use modified cultures as the inoculation fluid.

(*b*) Experiments with cultures which had been exposed to heat and partially destroyed or weakened.

The bacillus coli icteroides was first employed in these experiments. The bacillus was grown in bouillon for from twenty-four to forty-eight hours at 37° C., then for twenty-four hours at 40° C., and then for twenty-four hours at between 45° and 50° C., and finally was exposed for five minutes at 55° C.

This fluid was found to cause a considerable reaction in a dog chosen as in the (*a*) experiments. The dog readily recovered, however, and bore larger doses than in (*a*) experiments. The period of decline of the temperature was not so long and the prostration not so marked. This dog after three months' treatment received a dose of twenty cubic centimetres of the living cultures of bacillus coli icteroides, grown for four days in bouillon at 37° C., and after a short period of sickness extending over five days recovered completely. A control dog was inoculated at the same time with the same dose and in the same manner. This control dog died in twenty-four hours.

This (*b*) experiment with the bacillus coli icteroides was repeated with the bacillus coli concentricus. Results similar to those obtained with the bacillus coli icteroides were thus obtained with the bacillus coli concentricus.

I now undertook a further step in the development of a method of immunization or vaccination against yellow fever, adapted for use in man, by determining whether a single inoculation of a culture, prepared as described under (*b*) experiments, would protect against a fatal dose of the living culture.

I inoculated a dog chosen as above described and of the same weight with one dose of fifteen cubic centimetres of the fluid prepared according to the (*b*) experiment with the bacillus coli icteroides, and when the reaction had completely disappeared inoculated the same dog again with a fatal dose of the living culture of the bacillus coli icteroides. The dog recovered after suffering a severe and protracted reaction. A control dog inoculated at the same time with the same amount and in the same manner died in about twenty-four hours.

This experiment was repeated with the bacillus coli concentricus, prepared like the culture used in the first (*b*) experiment, and it gave a similar reaction. The dog was injected with the single large dose of the fluid thus prepared, and was enabled to receive a deadly dose of the living culture of the bacillus coli concentricus with a moderate reaction, from which it completely recovered.

This experiment was also repeated with the culture of the bacillus icteroides sent to me by Dr. Jose Sanarelli. This culture was treated in the same manner as the bacillus coli icteroides in the first (*b*) experiment. The resulting modified culture fluid was injected subcutaneously into a dog weighing forty-five pounds, chosen as above described, in a single dose. After the period of reaction had completely subsided, this dog received a fatal dose of the living bacillus icteroides (Sanarelli), and after a moderate period of reaction and some prostration, completely recovered its usual health. A control dog was inoculated in like manner at the same time and with the same fatal dose, without having received any previous inoculations, and this control dog died in twenty-four hours.

The last experiments under (*b*) were made with a fluid consisting of equal parts of cultures of the bacillus coli icteroides, the bacillus coli concentricus, and the bacillus icteroides (Sanarelli) mixed together after having been prepared in the same way as the culture of the bacillus coli icteroides was in the first (*b*) experiment.

This mixed fluid gave practically the same results as the other (*b*) experiment fluids when injected in one large dose, and protected the thus immunized dogs against a fatal dose of a mixture in equal parts of the three living cultures.

The next step in the development of a prophylactic or immunizing fluid which could safely be used on man consisted in seeking to obtain a fluid in which all the bacteria were surely dead.

(*c*) Experiments with cultures which had been grown for four days, then killed by exposure, and further disintegrated.

The cultures were first grown for four days at 37 C., then exposed to a temperature of between 50 and 60° C. for a period of fifteen minutes. This period of exposure was repeated until no colonies appeared on plate culture media.

The fluid was first prepared with the bacillus coli concentricus. A dog was gradually immunized by a graded series of doses after proper intervals of rest, and after three months from the first inoculation of this (*c*) experiment fluid was enabled to bear a fatal inoculation of the living culture of the bacillus coli concentricus. This experiment of graded doses to produce immunization and a final fatal dose was repeated with a like result with the bacillus coli icteroides.

I then attempted to inoculate with one large injection and after the reaction to give a fatal dose. This experiment has not been so successful as have those under the (*b*) experiments.

Three dogs were inoculated with a single large inoculation of the (*c*) experiment fluid, prepared from the bacillus coli concentricus. Of these, two remained alive and one died one week after the control dog died.

The (*c*) experiment fluid was in a like manner prepared with a culture of the bacillus coli icteroides.

The dog which received a single large inoculation of this fluid was enabled to receive the fatal dose of the living culture of the bacillus coli icteroides and recover its normal health after a period of reaction.

The (*c*) experiment fluid was also prepared from a culture of the bacillus icteroides (Sanarelli).

Two dogs have been inoculated with a large dose of this fluid; after the period of reaction had completely subsided they were again inoculated with a fatal dose of the living culture of the bacillus icteroides (Sanarelli). They both recovered their normal health after the period of reaction. The control dog died in twenty-four hours.

The (*c*) experiment fluid was finally prepared from a mixture in equal parts of the three cultures—bacillus coli concentricus, bacillus coli icteroides, and bacillus icteroides (Sanarelli).

The fluid so prepared was injected subcutaneously in one large dose into a dog, and after the period of reaction had passed the same dog received the fatal dose, made up of a mixture in equal parts of the three living cultures. This dog recovered after a longer than usual period of reaction and depression. The control dog received the fatal dose of the three living cultures without any previous inoculation, and died in twenty-four hours.

The experiments which I have here briefly recorded prove with apparent conclusiveness that if the bacillus coli icteroides, the bacillus coli concentricus, or the bacillus icteroides (Sanarelli), either singly or in combination, are the agent or agents of infection and death in yellow fever, they, by the evidence of the results of these experiments, form a basis from which an immunizing or prophylactic fluid can be perfected, and which can be safely applied to man to prevent yellow-fever infection.

These notes are published more to indicate the work that is being done at the laboratory of the New York health officer's department than from an idea that the investigations herein stated have been completed or brought to a satisfactory resting-place. The exigencies of circumstances have made it necessary to state a few of the facts ascertained in our work upon yellow fever, and publish the remainder when the investigations have been completed.

THE ABORTIVE TREATMENT OF TYPHOID FEVER—A QUESTION OF DIAGNOSIS.

By JOHN ELIOT WOODBRIDGE, M.D.,
CLEVELAND, OHIO.

From the opening of the discussion on the abortive treatment of typhoid fever to the present time, every orator and essayist who has discussed the subject from theoretical knowledge only has condemned it as irrational, unscientific, and incapable of producing the results which its advocates claim for it. Their arguments have been drawn from what were supposed to be fixed and immutable laws of pathology. Their reasoning has been cogent and convincing, voicing the latest and strongest interpretations of science, supported by the experience and observations of centuries, aided and abetted by every recognized authority on the subject, and by the fact that no observer has yet been able to destroy *in vitro* the specific cause of the disease by any known agent not inconsistent with human life. Their position has been further strengthened and fortified by the fact that hitherto all efforts to discover and establish a curative treatment for typhoid fever had proven disastrous failures.

Per contra, those who (possessing proper equipment) have thoroughly tested the method are unanimous in its praise, and those who have had the largest experience in the management of the disease under the older methods, supplemented by such adequate experience with the abortive treatment as to entitle them to speak with authority, are its most enthusiastic advocates and do not hesitate to report their cases of *aborted* typhoid fever or to aver that the treatment "*aborts* the disease."

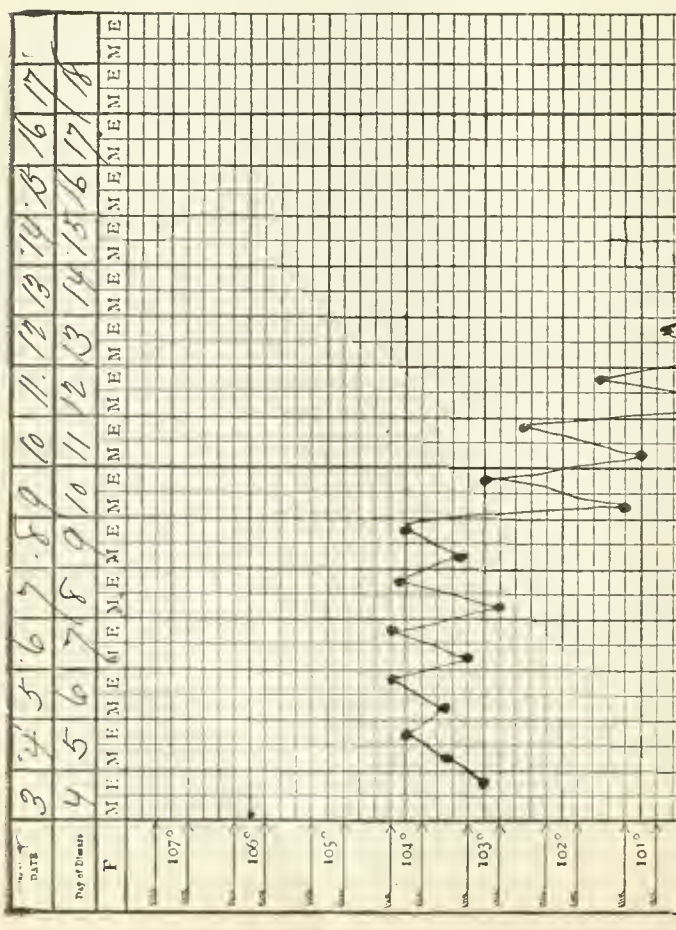
As the custodian of the reports, clinical charts, and histories of cases which fully confirm these averments, it is my duty to summarize enough of this mass of evidence to answer every argument which those who present the negative may advance. This paper deals directly or indirectly with their last and least defensible position, viz., that the evidence of the value of the treatment under consideration is based upon "errors of diagnosis."

Typhoid fever is practically universal and omnipresent. It is one of the few diseases with which we meet at every step in our professional careers, and when true to type it is one of the easiest diseases to diagnosticate. It is therefore an insult to the intelligence of the medical profession to ask it to entertain the theory that hundreds of its most progressive members could treat more than nine thousand patients under a mistaken diagnosis of typhoid fever. The argument is therefore puerile, fallacious, and utterly unworthy of serious consideration, and would never have been advanced save for the firmly grounded opinion that it is impossible to *abort* any of the specific infections; but, having been advanced, it must be frankly answered and effectually refuted,—not in defence of a theory as such, nor yet alone because the argument is an indirect assault upon the reputation of a great number of most respectable physicians, but because the continued discussion of the subject means so much to the victims of certain microbic diseases.

Those who realize the difficulties which always attend the collection of statistics in favor of any new method of treating disease will be surprised to learn that there have been reported ninety-four hundred and seventy cases of typhoid fever treated by the method

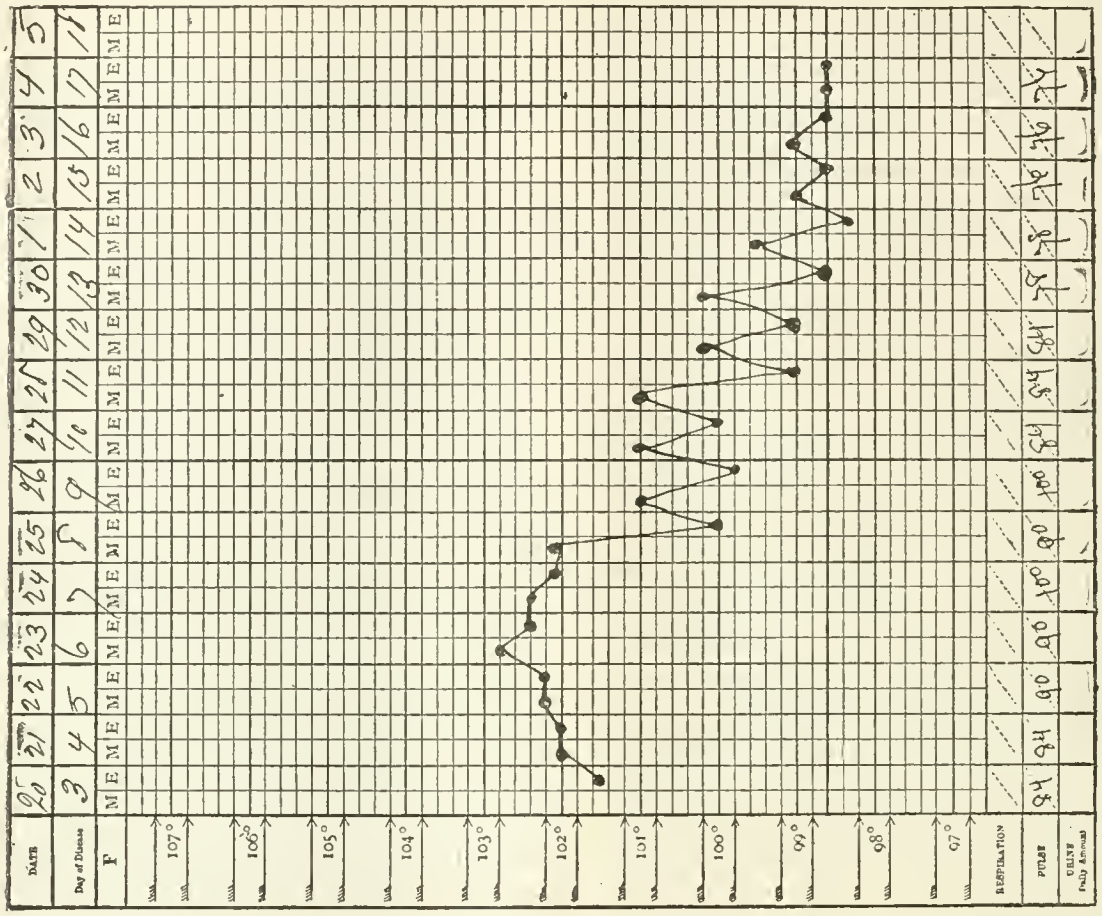
under consideration, with one hundred and seventy-nine deaths, or a death rate of 1.89 per cent., and an average duration of illness of twelve and seven-tenths days in fifty-five hundred and sixty-one of the cases that ended in recovery. These physicians report sixty cases of pregnancy complicating typhoid, in two of

CHART I.



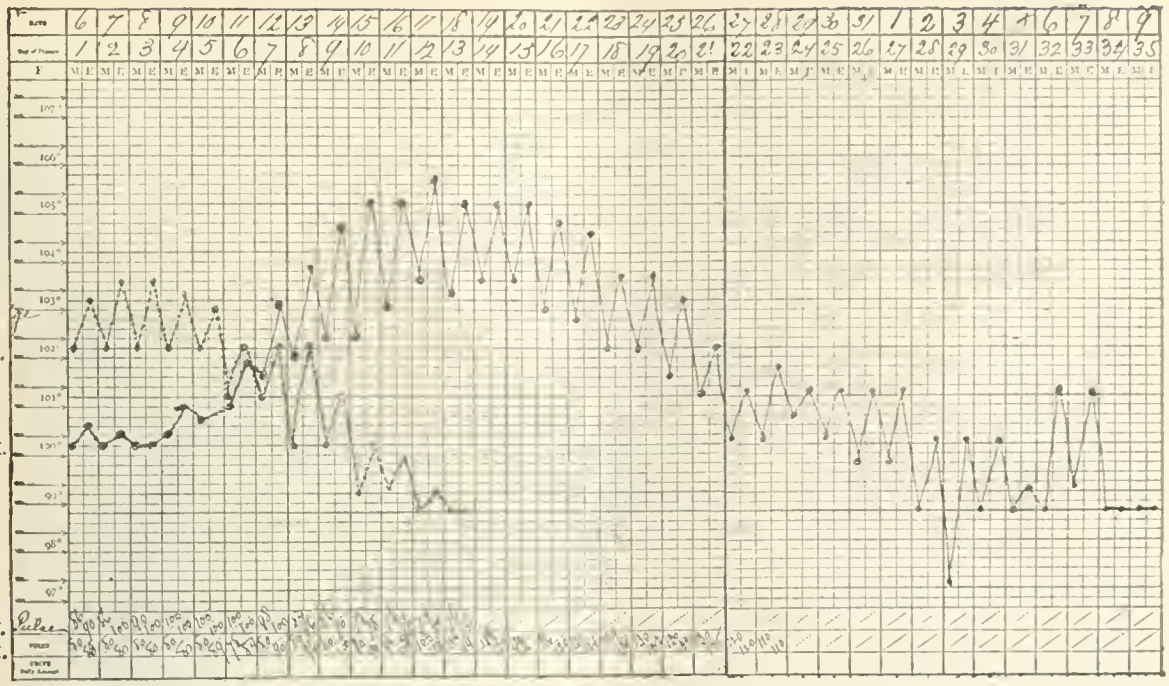
CASE I.—John L——, aged 25, admitted September 3, 1896; diagnosis, typhoid fever. *History.*—Patient boarded in same house with Mrs. Joe E. A. (Case IV.). He had been on a visit to a neighboring town twenty-five or thirty miles distant; returned home with fever. I saw the patient on the fourth day of illness, in my office. *September 3d.*—Temperature, 103; pulse, 90. Put him under Woodbridge treatment. Temperature touched normal on morning of twelfth day of treatment and sixteenth of disease. Had rose spots. One of five cases which occurred in the same house. Patient had no troublesome diarrhœa. Had some tympanites. No delirium. Rapid convalescence.

CHART II.



CASE II.—Mrs. Joe E. A——, aged 23, admitted September 20, 1896; diagnosis, typhoid fever. Medicine, Woodbridge method. *History.*—Patient moved into the house where No. 1 was sick. She developed fever on September 20th. Temperature, 101.5; pulse, 84. Temperature touched normal on ninth day of treatment and eleventh of disease. Uninterrupted recovery.

CHARTS III. AND IV.



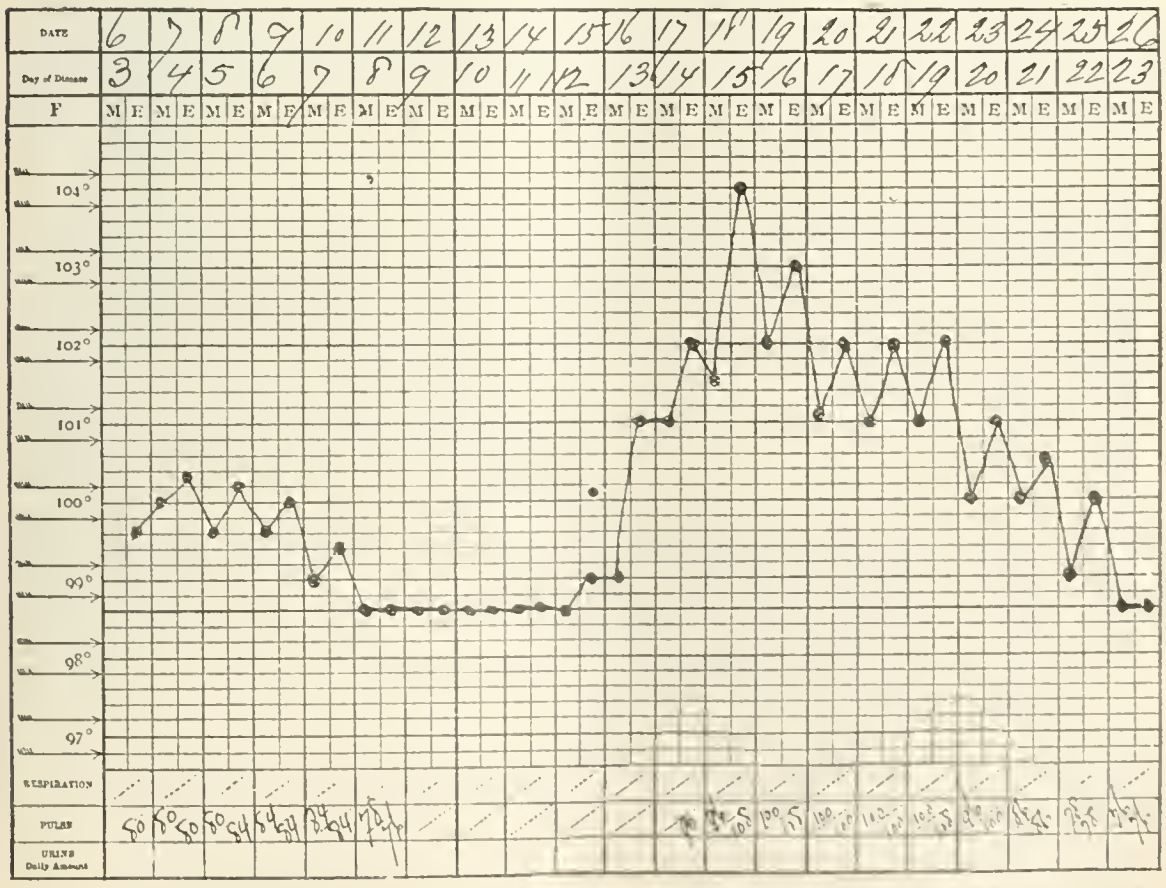
Case III.—Estelle H——, aged 10, admitted October 6, 1896; diagnosis, typhoid fever. Brand method.

History.—Sister to Mrs. Joe E. A. (Case II.), daughter to Mrs. J. C. H. (Case V.). Second case in same family, third in same house. I saw this patient on the first day of the disease and put her on the usual remedies, as she was a robust, healthy girl, and as Case IV. was also sick I decided to see the difference in effect of treatment. On the tenth day her temperature was so high and her general condition seemed so desperate that I called in consultation Dr. J. D. Valliant, who confirmed the diagnosis and approved the treatment, *i.e.*, Brand's method—calomel, tincture of iodine and carbolic acid, arterial sedatives, and opium. No hemorrhages occurred; had well-developed typhoid rash, tympanites, diarrhœa, wild delirium, and carphologia. She finally recovered after thirty-five days of intense suffering—a mere skeleton.

Case IV.—Mr. Joe E. A——, aged 28, male, admitted October 6, 1896; diagnosis, typhoid fever. Result, cured in twelve days. Woodbridge method.

History.—This patient was taken sick on the same day and in the same house as No. III. Patient was at work at his usual vocation on the eighth day after the temperature touched normal.

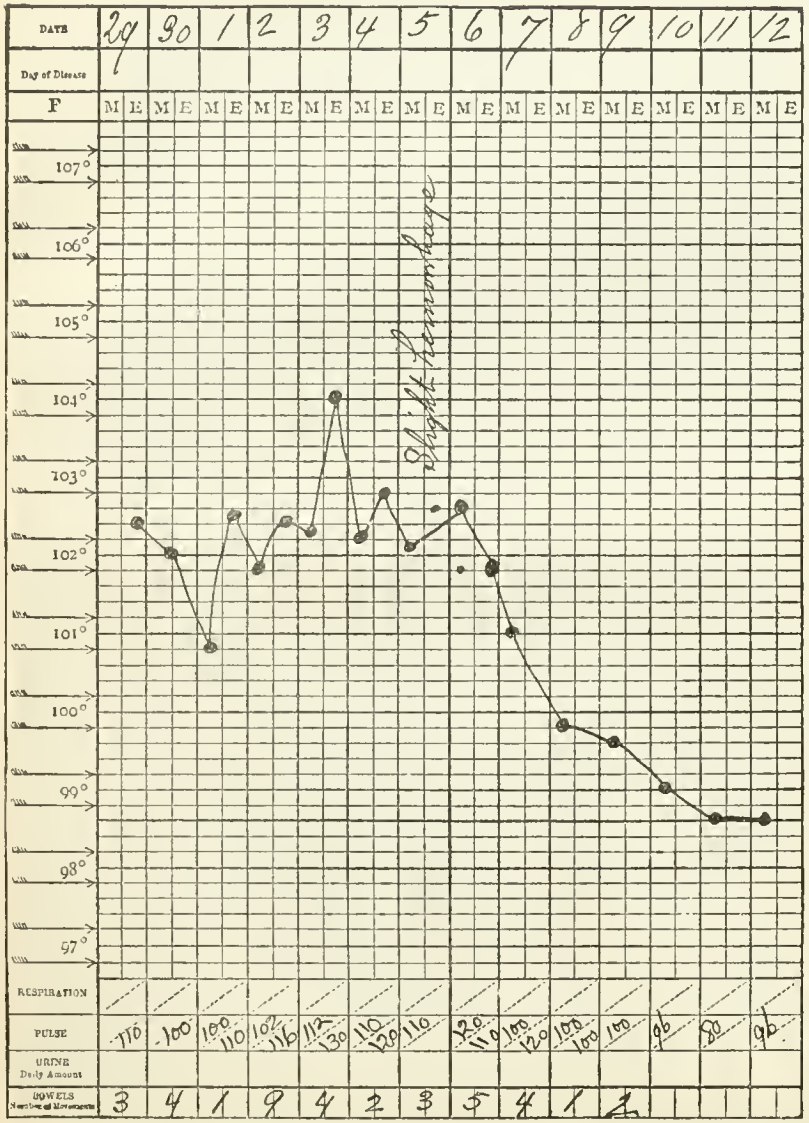
CHART V.



Case V.—Mrs. J. C. H——, aged 46, admitted November 6, 1896; diagnosis, typhoid fever. Woodbridge method. Mother and nurse of Mrs. J. E. A. (Case II.) and of Miss Estelle H. (Case III.). Case of relapses from indiscretion in diet.

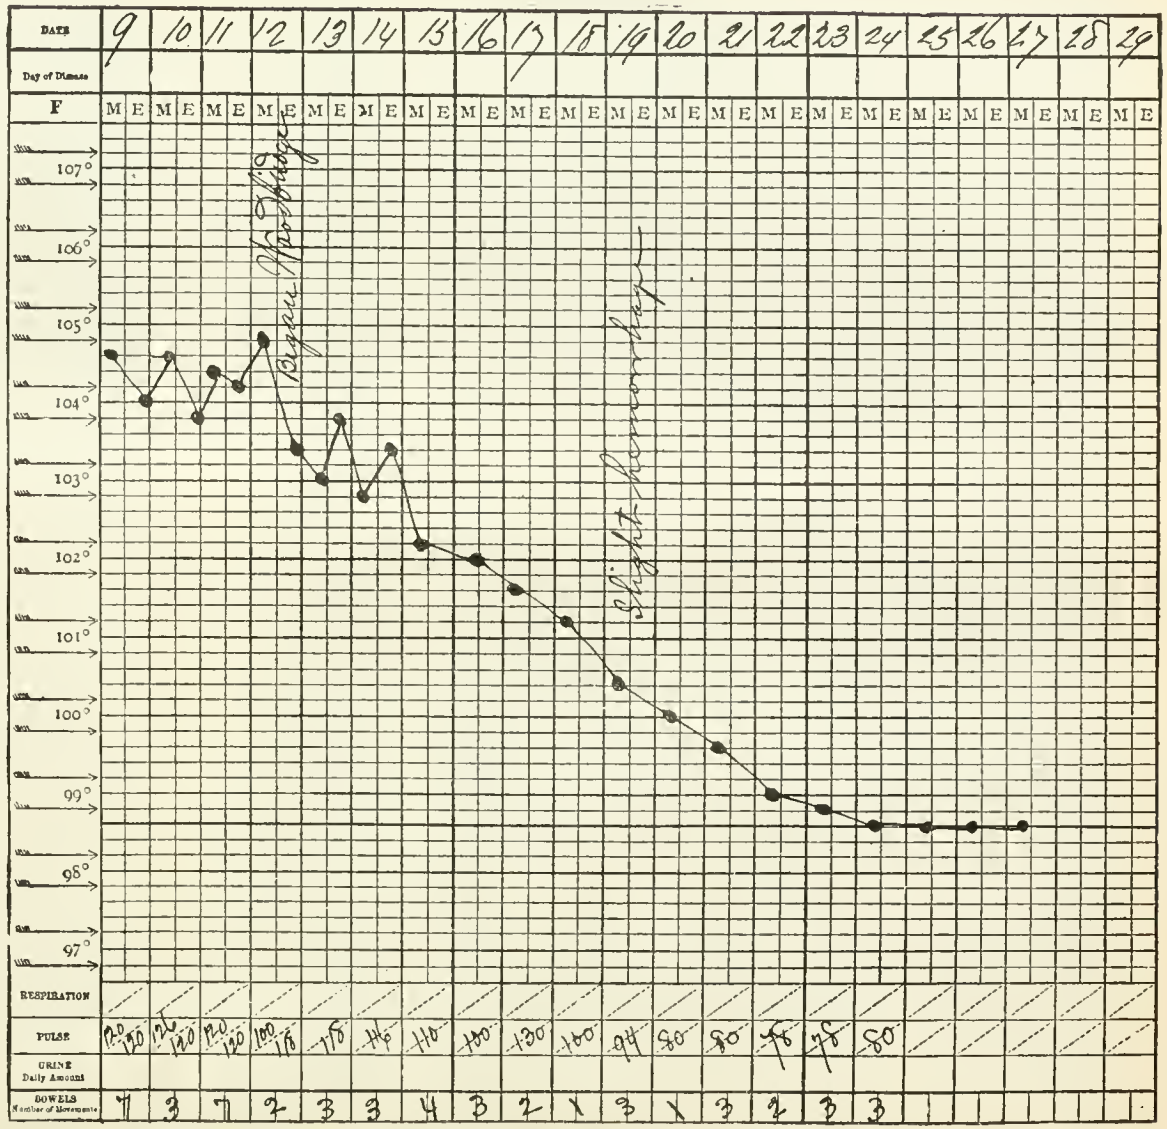
History.—Nursed her two daughters and her son-in-law through attacks of typhoid. Patient attacked on November , 1896. Put her on Woodbridge treatment immediately. Temperature ran very low and touched normal on seventh day of disease and fifth of treatment. Dismissed patient. Was called on thirteenth day. She had eaten heartily of turnips and turnip greens on twelfth day. Found her pulse 90, temperature 102. Persisted with the treatment, and temperature touched normal on morning of tenth day of relapse. Rapid convalescence. No constipation.

CHART VI.



Mrs. Annae K——, aged 29; diagnosis, typhoid fever. The patient contracted the disease while nursing her sister.

CHART VII.



Miss Amelia H——, aged 18; diagnosis, typhoid fever. Temperature touched normal tenth day after beginning Woodbridge treatment.

which the women aborted and died, eight aborted and recovered, and fifty carried their children to full term.

More than two hundred of these observers treated more than six thousand cases, with twelve deaths, or an average of more than thirty cases each, with an average death rate of less than one-fifth of one per cent. A very large percentage of these cases was treated during epidemics or local outbreaks of the disease. In many instances several cases occurred in a single house or family (see Charts I. to V.), and in some of these the physician conducted control experiments (see Charts III. and IV.), one of which is presented in the accompanying series of charts, for which I am indebted to the kindness of Dr. Nixon, of Killeen, Tex. They are self-explanatory and offer many interesting features.

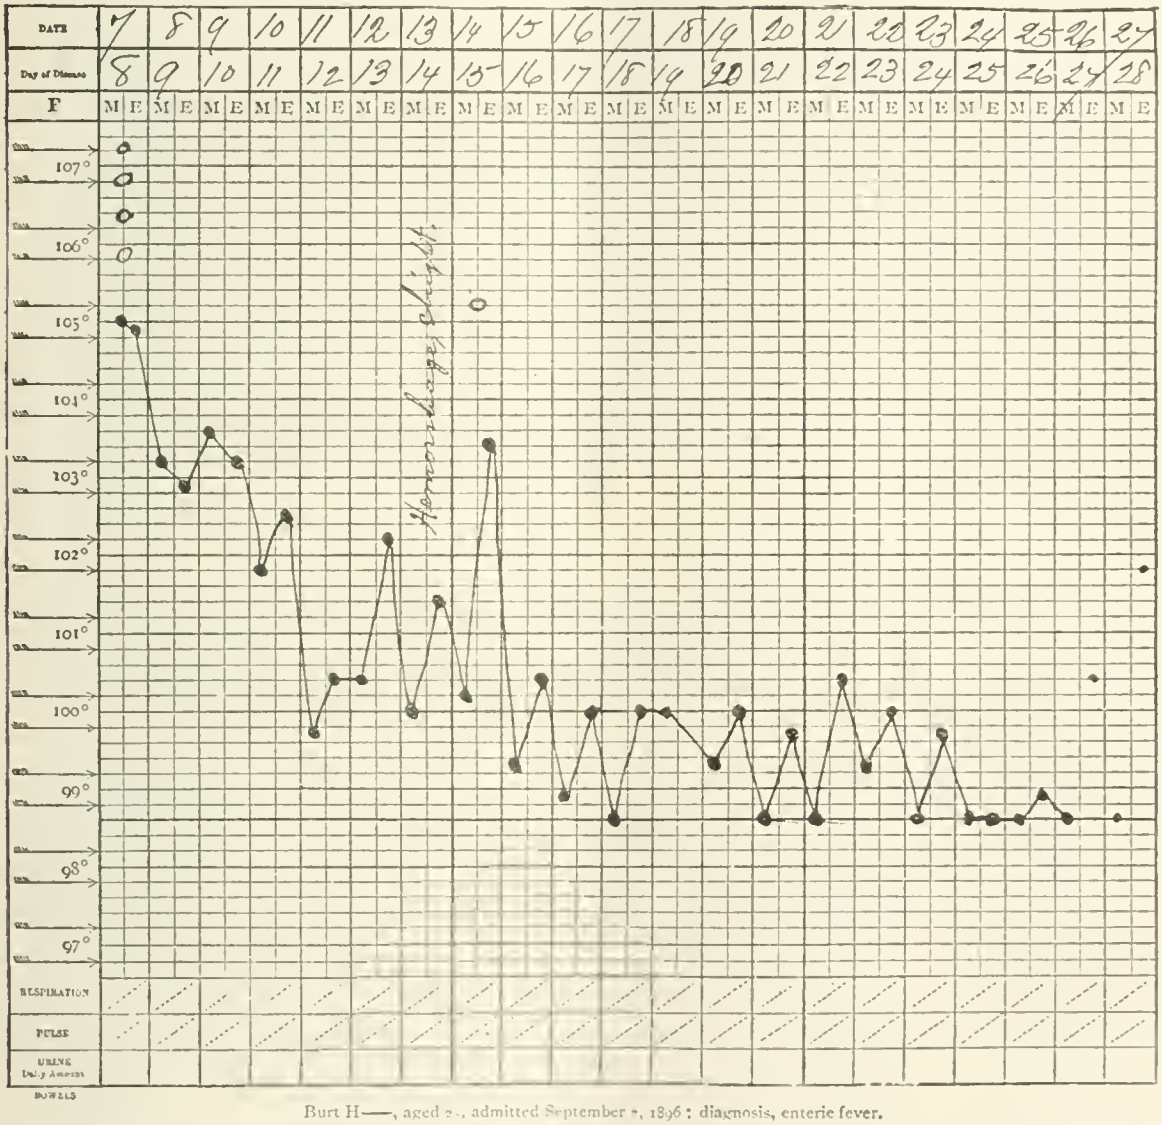
It will be observed that the control case, Chart No. III., treated by the Brand method, was, during the first week of illness, an exceedingly mild case. It is of course impossible to prove a negative, *i.e.*, that what did happen would not under other circumstances have occurred, but to those who are familiar with the effects of the abortive treatment no argument will be necessary to prove that this patient might have been cured just as quickly as any of the others in the series—that the disease might in fact have been *aborted* as quickly as was the primary attack in Case V., which is also interesting as having been jugulated in five days. it would, without the relapse, never have been heard of, but would have been lost to science, as are thousands of similar cases.

Charts VI. and VII. are of cases of Dr. Steinle, of Burlington, Iowa, treated in the same house, and, besides the fact that there were present pathognomonic symptoms of typhoid fever, both patients had slight intestinal hemorrhages.

The clinical histories from which these charts are taken show a large number of similar cases in which intestinal hemorrhages have occurred without interrupting, and apparently without retarding, recovery. They show also many cases in which the primary attack was aborted, the relapse presenting all of the pathognomonic symptoms of the disease accompanied by intestinal hemorrhage, which in a few instances proved directly fatal and in others was followed by perforation, peritonitis, and death, the autopsy revealing the characteristic lesions of typhoid fever.

Chart VIII. illustrates a case in which the treatment, never properly applied, was modified about the third day by the omission of the ingredients of which this patient stood in greatest need. Nevertheless the temperature dropped rapidly from 104.8° F. on the eighth day of illness to 99.7° F. in four days and to normal in nine days, but the patient suffered a relapse and died. At the autopsy a large amount of fæcal matter was found in the small intestines, and recent as well as old ulcerations of Peyer's glands, in one of which was the perforation which caused the death.

CHART VIII.



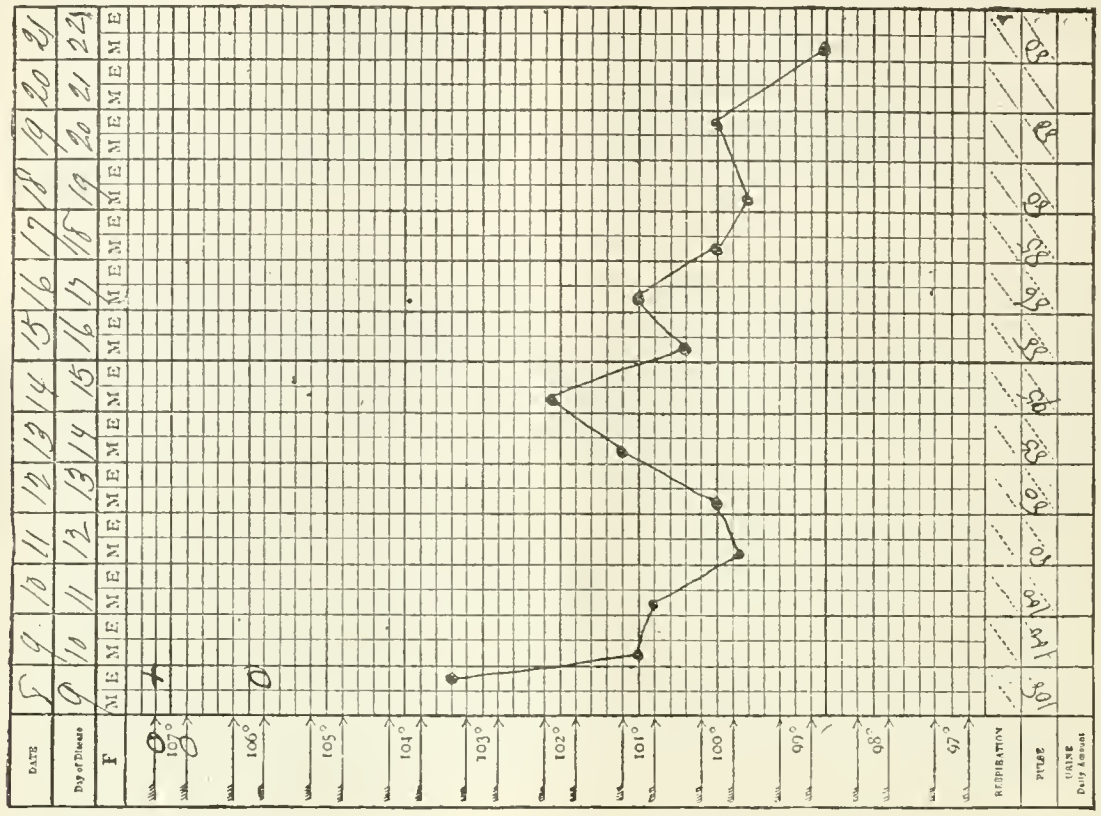
Burt H——, aged 2-, admitted September -, 1896 : diagnosis, enteric fever.

The clinical diagnosis has been verified in a large number of instances by the diazo reaction of Ehrlich. Charts that were published in previous papers, as well as Charts IX. and X., in this series, show the effect of treatment in these cases. The clinical diagnosis has also been verified by the serum test of Widal. Charts XI. and XII. and the following clinical histories illustrate the effect of treatment in a few of these cases.

Medical History Book of ——— Hospital, page 793.—"Admitted November 17th. Treatment commenced November 18th. Temperature normal November 24th. Discharged cured December 16th. Treatment began when history showed illness of one week's standing. Positive Widal test.

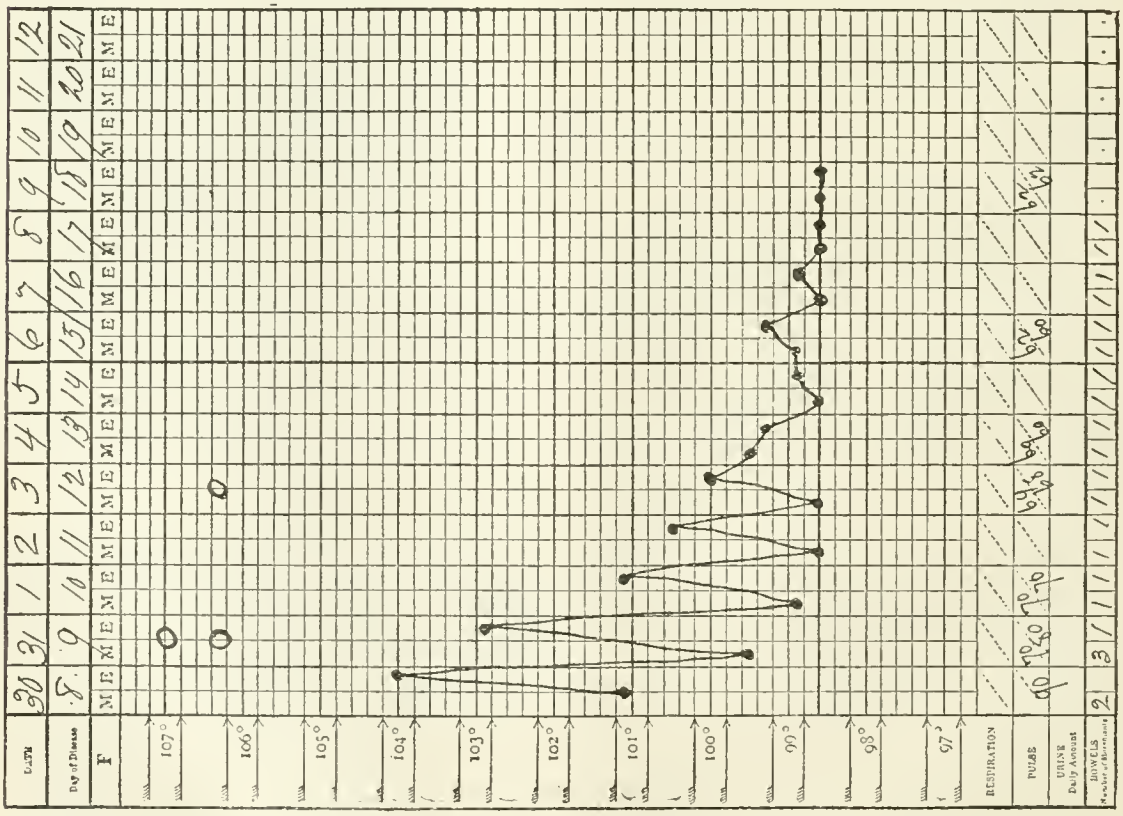
Page 791.—"Admitted November 8th. Treatment began November 10th. Illness of one week's standing. Temperature normal November 30th. Discharged December 14th, cured. Positive Widal test."

CHART X.



Miss W——, aged 12, admitted April 8, 1897. Widal's reaction of serum on Koch-Eberth bacilli positive; diagnosis, typhoid fever. Woodbridge method. Diet, milk and broths.

CHART IX.



Clarence R——, aged 17; diagnosis, enteric fever.

CHART XI. OF CASE NO. 9,057.

the capsules during the first two weeks of treatment. Although the temperature fell rapidly to nearly or quite normal and remained low all of the time, there was considerable tympanites, which disappeared promptly after a few hours of heroic medication. There was a slight hæmaturia late in the disease, but the patient felt remarkably well throughout his illness, his bitterest complaint being of an insufficient allowance of food. (Reported by Dr. H. B. Ormsby, of Goodrich House, Cleveland, Ohio.)

In case 9,058 not only was clinical evidence of typhoid fever presented, but the blood responded positively and characteristically to Widal's test and the urine to the diazo reaction of Ehrlich. (Reported by Dr. H. B. Ormsby, of Goodrich House, Cleveland, Ohio.)

These are a few items of evidence taken almost at random to prove a truth that needed no proving. The mere fact that so large a body of physicians continues to use this treatment is sufficient guarantee of its value. The honorable position so many of them have attained is ample assurance of their ability to diagnosticate typhoid fever, and their statement of the fact is apodeictic evidence that the treatment aborts the disease.

RATIONAL ETHERIZATION—A STATISTICAL STUDY.[1]

By WALTER BROOKS BROUNER, A.B., M.D.,

NEW YORK.

Recent medical journals throughout this and other countries have contained many interesting articles in reference to anæsthesia—the value of ether *versus* chloroform, the indications and the contraindications of their use, etc., have largely been entered into, but in none of recent origin has sufficient stress (emphasized by tangible proof) been laid upon the vital essential to successful ether anæsthesia, namely, the amount of ether employed. By successful ether anæsthesia I here mean an easy, gentle, unrevolting administration of ether till complete anæsthesia has been attained; the continuance of the anæsthesia during the operation, with a minimum of annoying complications; and the subsequent recovery of the patient with a minimum of the too common sequelæ of ether administration, viz., nausea, vomiting, bronchial trouble, and nephritis.

I purpose to speak to-night mainly upon the amount of ether to be employed, as modified by certain conditions, and incidentally to give a brief *résumé* of the influence upon the kidneys, the stomach, and the bronchi. Before presenting the statistical table which is the basis of this brief paper, a few introductory remarks will be in order. The subject of anæsthesia of any sort is one that will ever be pregnant with interest, but those who by precept and practice have become accustomed to the use of ether preferably as an anæsthetic will agree that too much time and study cannot be devoted to the subject; for it is a well-known fact that that which is really almost as vital to the success of an operation as the ability of the operator is too often intrusted to incompetent and inexperienced hands. Hence it is that to-day with our increased experience it is not strange that the proposition has been made to include anæsthetization in the already broadening field of specialism. I venture to predict that before long all of our medical schools will see the necessity of including the subject in their curricula.

I make bold to-night, in all seriousness, to make the assertion that no man should count himself thoroughly competent to administer an anæsthetic, ether especially, until he has had the same anæsthetic administered to himself. If while hospital interne I had any success at all in the administration of ether, if I won the reputation for gentleness in ether administration, and if I merited the gratitude of those whom I etherized, it was largely due to the sympathetic bond which held me to my patient. It is difficult to give expression to the awful sense of impending dissolution—the mental agony that seizes upon one in the futile struggle for air—more air! as the cone is held tightly over one's face and one is held in a vise-like grasp of a sturdy attendant, who, octopus-like, embraces you while you are being rapidly and forcibly smothered—technically asphyxiated. A more inhuman, a more revolting picture is hard to conceive. My blood has fairly boiled within me as I have seen, alas! too often, the so-called "force method" of etherization employed. It is unnecessary, it is cruel; nay, more, it is positively injurious—even affecting the issue of the operation.

You have now an explanation of column four of my statistical table, which shows that it required an average of eight and a half minutes to produce complete anæsthesia. Contrast this with the "force method" of a certain well-known physician who said that in over one hundred tabulated cases the average time required to produce anæsthesia was one minute and thirty-seven seconds. Picture if you can, the mental agony of those poor victims.

Method to be Employed.—The more simple and the less complicated the paraphernalia the better. I like to have near by a working hypodermic with strychnine, digitalis, atropine, glonoin, ether, nitrite of amyl pearls; also a good simple mouth gag, preferably a piece of wood, shaped like the handle of a tablespoon somewhat flattened and broad; a pair of tongue forceps and a curved needle threaded with stout silk, ready for use in fishing out the tongue. This latter obviates the sore thumbs of the etherizer and a condition more painful than mumps which a patient experiences upon awakening after the etherizer has braced his thumbs forcibly against the angle of the patient's jaw.

Some claim that the selection of a cone is very important. My humble opinion is that the simplest sort of a cone far exceeds the heavy and complicated cones so highly recommended. The cone I used in my service was a butcher's straw sleeve, something like the gauntlet of a glove, with the distal or wrist end packed fairly firmly with a piece of gauze; later on in my service one made of rubber,[1] of the same glove-gauntlet shape, was employed. A prime essential is a graduated ether bottle with a proper dropper inserted; this enables us to control exactly the amount of ether employed. The ether should be absolutely pure and fresh for each case.

Amount of Ether to be Used.—This I take to be the determing factor in the untoward sequelæ so often complained of. If after operation the patient is extremely nauseated, if he vomits much, if he subsequently has bronchial or nephritic complications, the chances are many that the ether was indiscriminately given; that, to use a common phrase, he was "soaked" with ether. A glance at the table here presented, which represents forty consecutive cases (not selected) occurring in the service of Drs. Abbe, Bull, and Murray, embracing all sorts of conditions of individuality and a variety of operations, shows that it required but an average of two and two-fifths ounces of ether for each operation, the average time of which was forty-eight and three-fourths minutes, and that it required but two and one-fifth ounces of ether to produce complete anæsthesia. The urine was from specimens ob-

[1] Read before the Society of the Alumni of St. Luke's Hospital, New York City, November 12, 1897.

[1] New York Medical Record, September, 1893.

tained twelve hours before and twelve hours after operation.

This small amount of ether necessary to keep the patient well under can be demonstrated with a little care. Of course in order to accomplish this the etherizer must devote his *entire attention* exclusively to the patient. It is surprising how easy it is to hold a patient quietly with just a drop or two of fresh ether added to the cone. It seemed to me to be not so much a question of the concentration of the vapor as it was *of ether employed.* It is always a comfort to an operator to know after his operation that he can practically eliminate the question of ether complication, if the anæsthesia has been carefully and conscientiously employed. A glance at cases Nos. 8, 9, 15, 16, 20, 26, and 40 is illustrative. I have ventured to go into detail and to append this tabulation even at the risk of tiring you, as I consider it highly instructive, for it presents on analysis and study much that is interesting. Thus, in cases Nos. 6, 10, 21, 28, 31, and 33,

of the frequency and regularity of adding a fresh drop. In all of the forty cases here presented I did not have one cyanotic patient. There was no vomiting during operation, no tongue to be replaced, and no stimulation necessary. It is also interesting to note that such an administration of ether is entirely compatible with the frequent admission of oxygen; that is, we may even withdraw the cone from the face for two or three minutes. The advantage of this is self-evident. As a rule, when a patient swallows his tongue it is due to a saturation of the system with ether.

As I have already stated, I believe that *the bad sequelæ of etherization are in direct proportion to the amount* observe here that, the patients being "alcoholics," a longer time proportionately was required to etherize them and so to maintain them. Sex also, as shown by the tabulation, has an appreciable influence. See cases Nos. 4, 5, 7, 9, 11, 12, 17, 32, 34, 38, 39. Roughly stated, we find that it requires a longer time to etherize women than men, but a relatively smaller amount of ether is required to accomplish etherization and to maintain them in such a state. This difference as regards the amount of ether required may be due to the influence of bodily weight.

The Effect on the Kidneys.—Barensfeld, Feuter, Wunderlich, Wier, Wood, Shrady, and others have

shown the effect of ether in producing albumin and casts, so that I will not enter into a detailed discussion, except to say that in my statistics only four cases had an appreciable degree of albuminuria produced; in three of these casts were found, but all cleared up in two or three days. See cases Nos. 12, 14, 28, 31, and 40. It is interesting to note that five patients had a trace of albumin prior to etherization, but *no* increase subsequent thereto. See cases Nos. 5, 10, 15, 16, and 27. Only three patients who prior to etherization had albumin showed an increase thereof subsequent upon the ether administration.

I wish, however, to call your attention especially to the effect of etherization on the specific gravity of the urine. Twenty-two showed an increased specific gravity, eleven showed a decreased, seven showed no change at all. So far as I have been able to ascertain, this subject of changed specific gravity has never been largely investigated. Would not this be an interesting subject for research on the part of hospital internes? I had intended investigating the relation of urates, phosphates, etc., but in my day I was too much otherwise occupied. *A propos* of still further investigation on the subject of etherization, I believe we have yet much to learn from experience. I need only to remind you of the possibilities of warmed ether, as suggested by Dr. Diaz de Leaño, of Barcelona, Spain.[1] As regards the evil effects of ether causing a reduction in bodily temperature, I am of the personal opinion that the baneful effects are overestimated, and, if active, can be readily counterbalanced by seeing that the patient is well covered prior to, during, and after the administration of ether.

Other Sequelæ of Etherization.—The influence on the bronchi was practically *nil*, no patient having contracted any bronchial disturbance. As regards the nausea and vomiting I regret to state that the detailed statistics relating to this subject were unfortunately mislaid. My recollection of them, however, is that actual vomiting occurred in less than ten per cent. of the cases. I believe that the ideal plan in all cases is to administer a small dose of Magendie's solution hypodermically, directly *after* ether has been withdrawn. This minimizes the tendency to nausea and vomiting, and gives the patient a refreshing sleep, thereby permitting the acute pain felt in coming out of ether to be deadened and securing a minimum of disturbance to surgical dressings, etc.

To conclude, I would summarize as a deduction from my experience the following:

1st. That etherization should be intrusted only to experienced hands.

2d. That a special cone is not necessary for successful etherization. The simpler and less complicated the apparatus the better.

3d. That the so-called "force method" of etherization is unnecessary, cruel, and ofttimes injurious.

4th. That vastly better results are obtained by a gradual, quiet administration.

5th. That the amount of ether employed should be minimized, preferably given drop by drop after anæsthesia has been fully established.

6th. That the evil sequelæ are directly proportionate to the amount of ether employed, and indirectly proportionate to the duration of the anæsthesia.

7th. That the so-called baneful after-effects on bronchus, stomach, and kidney are largely overestimated, and in a large degree controllable.

8th. That women require a smaller amount of ether though a longer time to produce anæsthesia than men.

9th. That alcoholic subjects require a longer time and amount of ether to produce anæsthesia and to maintain it.

URINALYSIS OF THE SIX-DAY BICYCLE RACERS.

By DOUGLAS BROWN, M.D.,

New York.

Believing that the apparently exhausted condition of the contestants in the six-day bicycle race, recently held at the Madison Square Garden, would yield some interesting results on the completion of a general urinalysis, I obtained, through the courtesy of the management, specimens from all the men, save one of the tail enders.

The eight leaders I examined on both the fifth and sixth days of the race. The differences between the two examinations, however, were very slight. The leader shortly before the termination of the race voided urine that was neutral in reaction and markedly charged with earthy phosphates. On the day previous the reaction was acid and the microscopical examination negative. Another specimen, from one of the first eight, showed an almost immediate change from an alkaline reaction to an acid on stimulating the rider by champagne during the last hours.

The urines were universally light in color on the last day. On the day previous two were of a dark yellow, but their specific gravities were 1.030 and 1.034 respectively.

The specific gravities were high, varying from 1.024 to 1.034, and averaging 1.028. Sugar was absent. The reactions were distinctly acid in ten, faintly acid in two, neutral in three, and faintly alkaline in one.

As to albumin, I was able to find faint traces in but two men, and one of these had been subsisting on a diet of three beefsteaks a day. He was next to the last man in the race, and had been sleeping almost as much each night as the leaders slept through the entire week of racing. The other was the fourth man. His urine yielded albumin on both days. He left New York immediately on completion of his work, and I have been unable to obtain another specimen. In his case I found under the microscope a few granular but no hyaline casts. In the other case I found a considerable amount of calcium oxalate but no casts.

As to the microscopical examination of the others, there was a large amount of uric acid and of amorphous urates in one (the man stimulated by the champagne). There were present amorphous urates in fair amount in three; calcium oxalate in one; amorphous and triple phosphates in considerable amount in two; triple phosphates in small amount in one. Six yielded either a very little mucus, some epithelial cells from the bladder, or absolutely nothing.

A large number of the men had undergone the same strain several times before, and yet the kidneys remained apparently uninjured. So it seems unfair to infer that time might bring the lesions out.

The several hearts which I examined while the men were resting showed an exaggerated action, and though the rhythm was normal the frequency was somewhat increased. Two of the hearts were slightly enlarged. Both men had previously engaged in similar contests.

Regarding their diet, there seemed to be a great diversity of opinion among the trainers. Some favored meat; others opposed it. Milk was an important element in all the cases I was able to inquire into. Oatmeal and apples they also seemed to agree upon. The winner consumed six dozen apples during the six days. Eggs were generally avoided. Some used beef tea and the proprietary beef extracts. Strychnine in one-thirtieth-grain doses was employed by some toward the end; also aromatic spirit of ammonia, champagne, and small doses of brandy.

None of the men, in spite of their almost constant seat in the saddle, complained of constipation; but

diarrhœa was more or less troublesome up to the end of the third day.

In conclusion, it seems fair to assume that in a contest of this sort, or in the case of any excessive bicycle riding, provided the diet is easily assimilated and slightly varied, but little will be felt by the kidneys. The real sufferer seems to be the heart, which either has developed or struggles to develop the necessary hypertrophy.

41 East Thirty-Third Street.

Progress of Medical Science.

The Radical Cure of Inguinal Hernia.—Drs. Nelaton and Ombredanne (*Presse Médicale*, July 31, 1897) present a new operation, whereby they divert the proximal end of the spermatic cord from the inguinal canal and cause it to run through a hole made in the os pubis. By this method they are free to treat the inguinal canal without regard to the cord and to close it more effectually than in the method practised by Bassini. The entire inguinal canal is slit up, the hernia reduced, the sac removed, and the spermatic cord freed from adhesions and from its connection with the fibres of the cremaster muscle. The posterior wall of the canal is then divided on a grooved director. Then a button of bone as large as a centime piece is removed at a point about one-third of an inch below the upper border; this is effected by means of a punch-like instrument. A chain saw is then passed through the hole and the bridge of bone is divided at its inner edge, preserving its periosteal connection. This bridge bone is then raised inward by means of forceps and the cord is dropped into the perforation, after which the bone is replaced and secured in position. The abdominal wall is repaired in two layers; the deep layer is closed with a continuous suture *en surjet*, carried in from the conjoint tendon to Poupart's ligament. With the same thread the superficial layer is closed from below upward. The advantages of this operation as a means of curing hernia appear to be undeniable. The altered course of the spermatic cord lengthens it, which allows of more complete descent of the testicle in those in whom the latter organ is unduly retracted. A disadvantage which may accrue is the danger of damaging the spermatic cord by a growth of new bone around it. This has not occurred in any of the cases operated upon by the writers; before the latter condition could advance far certain pressure symptoms would be noticed, such as varicocele and œdema; should these symptoms occur there would then be time to liberate the cord by cutting a channel downward and dropping the cord beneath the bone.

Functions of the Thyroid Gland.—Dr. de Cyon reported to the Academy of Sciences of Paris, September 21, 1897, that he had made numerous experiments to determine the physiological relations between the nerves of the heart and the thyroid gland. He thinks that he has discovered two important functions of this organ not previously known. First, the thyroid gland produces iodothyrin, which accelerates the functioning of nervous centres which regulate the beating of the heart and the circulation of the blood. The function of the thyroid gland aids in transforming the salts of iodine in the blood into an organic compound, which is iodothyrin, and in relieving the nervous centre of an exceedingly dangerous toxic substance. The heart, by the intervention of the nerve filaments that it sends to the two laryngeals, directs the production of iodothyrin indispensable to its normal functioning. Second, the thyroid bodies, situated at the entrance of the carotid arteries into the cranial vault, constitute an apparatus intended as a protection to the brain against the danger of a sudden flow of blood: as the latter are provoked by too great heart action or by a notable contraction of the circulatory vessels. This preservative function of the thyroid glands is likewise ruled by the heart. In occasioning marked dilatation of the thyroid vessels, the heart intervenes as a safeguard of the cerebral organs either (*a*) in working, so to speak, the sluice gates in case of sudden danger, or (*b*) in increasing the production of iodothyrin in the case of persistent danger. Two important points in the treatment of goitre resulted from the researches of Dr. de Cyon. In the vascular and hyperæmic form of this affection, it is necessary carefully to avoid the employment of thyroid product and to have recourse to the internal employment of iodine. On the contrary, the thyroid products will be very useful in cases of atrophy and of strumous cachexia. In cases of immediate danger section of the expressor nerves in the vascular forms of goitre, and of the sympathetic nerve in the atrophic forms, may be tried; but for these atrophied forms, extirpation of the gland will always have a more immediate and lasting effect than section of the sympathetic nerves.

Colporteur's Tic.—At a recent clinic Dr. Grasset (*Nouv. Iconogr. de la Salpêtrière*, 1897, No. 4) showed a patient with distinct professional polygonal spasm which differed from the ordinary type of functional spasms, convulsive tics, paramyoclonus, and the various forms of chorea. The spasm was somewhat complex. At its maximum the left arm was drawn in closely to the trunk, while the right was thrown backward. The muscles involved seemed to be the trapezius, the left pectoralis major, the sterno-mastoid and the dorsalis major on the right side, which were thrown into a state of clonic convulsions. Such a mixed or crossed convulsive seizure has not hitherto been described. After careful analysis the spasm was classed as one belonging to the choreic movements designated as tics. In a certain sense this tic must be regarded as functional, since the patient states that the movements involved were just such as would be called into play in attaching his package of books over the left shoulder in the occupation which he had followed for many years.

Werlhof's Disease in the Chronic Form.—An instance of this rather rare variety of hemorrhagic purpura, to which Marfan specially directed attention several years ago, is recorded by Drs. Apert and Rabé (*La Bul. Méd.*, No. 94, 1897). The subject was a boy about fourteen years, in apparent good health, without anæmia or weakness, but who, besides having frequent loss of blood from various mucous surfaces, presented finely pointed hemorrhagic eruptions and violaceous ecchymoses on various portions of the body. The following treatment was given: Citric-acid lemonade at discretion; avoidance of violent exercise; a teaspoonful of a forty-per-cent. solution of calcium chloride in a glass of water at the beginning of each meal. The morbid symptoms and the lesions disappeared eight days after this treatment was begun. The following conclusions are drawn: 1. There is a morbid type of purpura which does not belong either to purpura hæmorrhagica or to the infectious purpuras. It approaches Werlhof's disease and differs from it only in its long duration. 2. It is in this type that are constantly observed the loss of retractility of the blood clot and the non-exudation of serum. 3. It is also in this type that chloride of calcium, recommended by Wright in purpura, seems to act with the most benefit. 4. We must distinguish from other forms of purpura the chronic form of Werl-

hof's disease. The confirming diagnosis is by examining the blood and finding non-retractibility of the clot. If the latter is present, calcium chloride in one or two gram doses should be advised.

The Injection of Artificial Serum as a Method of Preventing Death from Extensive Burns.—The serum employed by Tomasoli (*Monatsschrift für prakt. Dermatologie*, Bd. XXV., No. 2) is a solution of sodium chloride and sodium bicarbonate. In a sixty-year-old woman with an extensive burn of the third degree, injections of from three hundred grams to one thousand grams of serum in three days did not prevent a lethal termination. In a second case, a young man, twenty years of age, with burns of the first, second, and third degrees, covering the entire right side of the chest, the right axillary space, the whole of the right arm, shoulder, back, and buttock, recovery took place. The patient received daily from March 13th until April 6th serum injections of from two hundred and fifty grams to five hundred grams each, and on May 3d left the clinic in an improved condition. Tomasoli experimented on animals. The hind legs of rabbits and dogs were burned or scalded by being immersed in water the temperature of which was gradually raised to 70° C. All animals burned in this manner died within thirty-six or forty-eight hours. Six rabbits of the same weight as those employed for comparison received injections of fifty grams of artificial serum immediately after being burned. Four of them died within the first twenty-four hours; the remaining two continued to live. Ten dogs, burned as has been described, were daily injected with from one hundred and fifty to two hundred grams of artificial serum. Only two of them died, and in these death occurred a few hours after they were scalded. All test animals that did not receive serum injections died within the first two days, notwithstanding the fact that they were selected and kept in a practically identical condition with the other cases. The writer also states that if serum be taken from one of these scalded dogs (not treated by saline injection), or if from the flesh of one of these animals an extract be made, and a definite quantity of this serum or extract, proportionate to the weight of the animal experimented upon, be injected into a healthy dog, the dog will die. On the other hand, if a dog in practically the same condition as the other one be injected with artificial serum immediately after receiving a lethal dose of the extract, this dog will not die.

On the Pathology of Infantile Diarrhœa.—Excluding the purely functional dyspeptic troubles, Baginsky (*Arch. f. Kinderheilkunde*, XXII., H. 3-6) distinguishes two forms of infantile diarrhœa: the catarrhal (the type of which is cholera infantum), and the real enteric or follicular (the type of which is dysentery). Intermediate forms are also noticed. Pathological anatomy: 1. The catarrhal forms show but slightly marked changes; slight swelling of the mucous membrane, abundance of mucus, more or less injection, slight or marked follicular swelling. Microscopically: Marked cloudiness of the epithelium of the stomach and still more so of that of the small intestine; often epithelial cells are cast off. Besides these are the interstitial changes ranging from a moderate round-cell infiltration to actual necrosis. The mucous membrane of the large intestine shows similar, generally more marked changes. 2. The enteric forms in mild cases show the following macroscopic changes in the large intestine: redness, hemorrhage, marked swelling, which swelling often consists of hemorrhagic zones of solitary follicles. Microscopically: Enormous infiltration of white cells, often to the serous coat of the intestine. The kidneys show marked parenchymatous and interstitial degenerations, which may lead to pyonephrosis; aside from these cases there may be a direct pyelonephritis. The liver shows marked fatty infiltration and degeneration. The lungs show broncho-pneumonia, which, in the writer's opinion, is never metastatic. Otitis purulenta is a constant accompaniment of this disease. Microscopic examinations give no ground for the belief that bacteria force their way to the blood-vessels or lymphatics from the intestines. In the kidneys the bacteria are found mostly in the uriniferous tubules. In the lungs sparse colonies are found in the capillaries and many cocci colonies in the alveoli. In the ears the diplococcus lanceolatus is found almost without exception. Cultures of the intestinal contents show in almost all instances the familiar bacillus coli and bacillus lacti. Besides these the bacillus pyocyaneus was discovered as the cause of a severe form of enteritis in a house epidemic. Summing up, the writer concludes: 1. The diarrhœal troubles of children caused by the summer heat are at the beginning only functional disturbances, and are changes in the motor and secretory functions of the gastro-intestinal canal, combined with abnormal chemism. Later, marked changes in the stomach mucous membrane occur. 2. The changes may range from catarrh to necrosis of the mucous membrane. 3. The follicular changes are entirely independent of the catarrhal. In cases of long duration the two changes are often combined; in such, ulceration is likely to occur. 4. There are no specific bacilli which cause the disease, but the ordinary saprophytes in the intestinal tract take on exceptional virulence. 5. Under exceptional circumstances bacteria not commonly found in the gastro-intestinal canal may cause diarrhœa. Such bacteria also cause marked changes in the mucous membrane. 6. The presence of these bacteria in other organs is not excluded; in fact, they are found quite often in the kidneys. Such transported bacteria can produce anatomical changes from inflammation to suppuration. Their course in the circulation is not the usual one; they occur very rarely here, and even then sparsely. 7. The severest lesions are produced by the bacterial products of fermentation, whether such products are poisonous or not. Such fermentative decompositions are either ammoniacal, as the result of by-products of decomposition of albumin, or are acid. These products, ammoniacal or acid, are the active causes of inflammation in the intestinal canal, and thus attack the wall of the intestine. They are also carried by the blood-vessels or lymphatics to the other organs, and particularly to the organs of elimination (liver, kidney, etc.), and in this manner cause inflammation, etc., there. 8. As a result of the poison thus engendered by the bacteria the whole organism is rendered less liable to withstand disease, and is a more easy prey to the inroad of other bacterial infections. Hence many complications may ensue in the diarrhœal diseases of childhood.

Treatment of Syphilis.—A. Neisser ("Die Einreibungskur," Volkmann's "klinische Vorträge," No. 199, December, 1897) considers that the results obtained in the treatment of syphilis by the inunction of blue ointment are referable, not to the comparatively small amount of the agent which actually makes its way through the skin, but to the inhalation of the vapor of mercury, which the warmth of the patient's body is constantly causing to be given off. He recommends that patients spend as much of their time as possible in a single, well-warmed room, taking as little outdoor exercise as is compatible with health, in order that they may be constantly surrounded by an atmosphere charged with the volatilized metal. His routine is to apply four grams of a thirty-three-and-one-third or fifty-per-cent. ointment, either at bedtime or on

rising (no friction is necessary), increasing the amount by one gram every tenth application and continuing the treatment for forty-two days. If the mouth is properly cared for by the plentiful use of astringent and antiseptic lotions, the author thinks that stomatitis and salivation should never be produced, although a mild degree of either does not in most cases require suspension of the treatment for any great length of time.

The Value of Operative Interference in Peritonitis arising from affections of the female sexual organs has till recently been recognized in only two forms of the disease, viz., the tuberculous and the perforative. F. v. Winckel ("Ueber die chirurgische Behandlung der von den weiblichen Genitalien ausgehenden Bauchfellentzündung," Volkmann's "klinische Vorträge," No. 201, December, 1897) recommends a much more general application of cœliotomy, and divides suitable cases into five classes: 1. Tuberculous peritonitis in all of its forms is curable by abdominal section with evacuation of the exudate, although it is still a mooted point as to whether or not the cavity should be flushed; and if the former, whether aseptic or antiseptic solution is more advantageous. The wound is to be completely closed and no provision made for drainage. 2. Gonorrhœal peritonitis, although usually not very severe, requires operation when pyosalpinx tumors exist. The size of the tumor determines whether abdominal section or an anterior or posterior vaginal operation is to be performed. Drainage is unnecessary in most cases. 3. Diffuse post-operative peritonitis is to be treated by a partial reopening of the original wound and evacuation of the pus. Drainage is indispensable. 4. Diffuse puerperal peritonitis indicates operation as soon as the pus formation has reached an appreciable degree; drainage is necessary, and most writers recommend irrigation of the cavity. 5. Perforation peritonitis is nearly always fatal unless prompt surgical measures are taken. Abdominal cœliotomy with free incision is to be performed as soon as possible, and the affected organ or organs are to be extirpated. Drainage is needed only when purulent foci are left behind.

The Attraction and Fixation of Diseased Organs to the Exterior.—The drawing of internal organs toward the exterior and fixing them in this new position constitute a recent departure of contemporaneous surgery. This method fulfils a double end: First, an organ may be fixed to the external wall, either in order to maintain it in position, or, when it is proposed to extirpate it, one may bring it near the skin and in this way avoid infecting the serous membranes which surround it. Second, sometimes the organ is maintained in this new position in order to bring about atrophy, as in the case of the thyroid gland, or in operating for hydronephrosis, or for tumors of the kidney, or of the vaginalis in cases of hydrocele, or of the ovaries and uterus. Operations having for their end the simple fixation of the organ to the wall have been practised on five organs—the kidney, gall bladder, liver, intestines, and uterus. In using this method we have in view either the conservation of the organ or else the rendering easier and less serious operations which are to be carried out later. In the case of movable kidney, Dr. Jaboulay, in 1895, reported his method, which was to incise the adipose capsule and fix it to the skin without any thread touching the renal substance. Little by little the edges of the incision and the fibrous capsule of the kidney became covered with cicatricial tissue, which held the kidney in place. This was really the proliferation of the fibrous capsule of the kidney. The fixation of an organ having for its object a secondary intervention has been applied to the liver affected with hydatid cysts or tumor. The fixation of this organ having been attained, removal of the tumor became very easy, fear of peritoneal infection was removed, and the treatment of a possible hemorrhage greatly simplified. Unfortunately this method can serve only for affections at the free edge of the liver, which alone can be drawn out. This method has been practised on the gall bladder a number of times. Bloch (*Revue de Chirurgie*, 1893) shows its superiority over cholecystotomy, which exposes to too much infection, and over methods which, in determining adhesions between the cystic peritoneum and the parietal peritoneum before opening of the gall bladder have the inconvenience of fixing the viscus to the wall by strong adhesions. Dr. Jaboulay operated on a woman who, having had intense hepatic colic, had the cystic duct obliterated by a calculus: from this there was a distention of the gall bladder, which rapidly attained the size of the fist. The bladder was very mobile and easily fixed to the wall after being incised and spread out. The patient left the hospital cured in six weeks. Atrophy of the viscus followed this exposure to the air. The clinical value of this operation can be clearly affirmed. These operations practised on the uterus have given excellent results. In all cases the uterus is fixed as a preparation for secondary intervention. We have never seen an instance in which the purpose was to bring on atrophy. When the uterus adheres to the abdominal wall, it is easy to enucleate fibromata which are present. Hemorrhages and infection of the peritoneum by the liquid of the cystic fibroma need not be feared. Necrosis of the pedicle is more rapid; the operation has also the advantage of not being done at the bottom of the cavity, where liquid stagnates. If one does not wish to extirpate the uterus, it is necessary to put it back when the wound has healed. In operations for artificial anus, infection of the peritoneum is rare except when the anus is the ending of a median laparotomy made for intestinal obstruction. In this case Dr. Jaboulay conceived the idea of drawing the intestine far out, in such a way that the incised parts would be far away from the cutaneous wound. In case of the incision having been made in the median line, a portion of the intestine drawn out was fixed for some days to a fold in the groin; then the intestine was permitted to enter voluntarily into the abdominal cavity. Another procedure, more simple and rapid, was to draw out a segment of the intestine and to fix the peritoneal covering to the edges of the incision without the thread traversing the parietal peritoneum. Without waiting for the formations of adhesions, the edges of the mucous membrane are fixed to the tegument at a sufficiently great distance from the edges of the cutaneous incision (about the width of two fingers). After absorption of the threads the mucous membrane enters into the interior of the digestive tube, the rupture being only temporary. This procedure is easy of execution and removes nearly all danger of inflammatory complications. In regard to fixation having for its object atrophy of the organs, we find that this method was first used for the thyroid gland, but it has since been applied to the testicle, kidney, spleen, and ovaries. Inversion of the vaginalis as a means for the radical cure of hydrocele offers certain advantages. It is given as one of the methods in the treatment of hæmatocele. Dr. Jaboulay reports one case of double hæmatocele, in which the wall of the vaginalis was very thick and of so fibrous a character that one naturally hesitated between decortication and castration. It was found that complete decortication was impossible, and double castration was refused. Dr. Jaboulay conceived the idea of operating as follows: The vaginalis was incised and the testicle was brought outward. The serous membrane then formed a large convex surface over the anterior part of the scrotum; it was cov-

ered with iodoform gauze. Under the influence of effusion it soon became covered with granulation tissue. The testicle entered by degrees into the interior of the sheath, and one could see only a slit in the tissue, without which it would have been impossible to distinguish between the vaginalis and the edges of the incision. The value of this operation is indisputable. It gives the same results as complete decortication. It is simpler to perform, and is free from the danger to the testicle. The only objection is the length of time necessary to obtain complete cicatrization. Atrophy of the kidney obtained in this way was more rare. Fixation of the spleen has been too rare to permit of our drawing conclusions. Fixation of the ovaries to the exterior has given good results. This is done in two ways. The ovary is spread out either on the abdominal wall or on the vagina. Under the influence of effusion, and probably also because of interference with the circulation of the pedicle, the ovary becomes atrophied. If it should be affected with a tumor, this either atrophies slowly or may be extirpated a short time after. This operation has the advantages of avoiding danger from hemorrhage or infection of the peritoneum by sutures; also of slow and progressive suppression of the ovaries and their secretions. The great inconvenience is that it can be applied only to patients in whom the ovaries are not bound down to other organs by adhesions. In conclusion, it may be said that these operative procedures are so new that we cannot as yet set a just estimate on their value. If we wish simply to transform a deep organ into a subcutaneous one, the secondary symptoms are notably simplified. The fear of infection or of slow hemorrhage is almost entirely removed. If we wish to bring about atrophy of the organ, the same advantages are present; we may also add to these advantages the rapidity of the operation and the possibility of performing it with fewer assistants and fewer instruments. If two organs are suppressed at the same time, their slow and progressive disappearance accustoms the organism to the cessation of their secretions. If one has in view the extirpation of one organ, the compensatory hypertrophy of the other can establish itself slowly. It is to be hoped that experience will encourage surgeons to follow this method.—Dr. Thévenot. *Lyon Médical*, August 29, 1897.

Surgical Suggestions.

Pressure Theory of Hernia.—The compression of the viscera by the abdominal muscles may produce a hernia suddenly or gradually at one of the weak spots of the belly wall. Some original or acquired defect of the abdominal wall at those places is present in some cases, is probable in all. In persons structurally perfect the abdominal wall may undergo changes from repeated internal pressure under certain circumstances, or from disease and other debilitating influences, whereby it is at length unable to withstand the distention to which it is subject. In those structurally imperfect defects may be so great as to give rise to early hernia. With defects of lesser degree the structures involved may undergo changes resulting from growth or from various debilitating influences, which diminish still further the strength of the abdominal wall till it no longer resists the intra-abdominal pressure. Hence the principal cause of hernia would appear to reside in imperfection of the structures which form the openings through which herniæ escape. But one factor alone is not as a rule sufficient to determine the descent of a hernia, and this is attested by the occasional presence of a congenital opening without a protrusion.—Macready.

Ballooning of the Rectum.—The phenomenon termed ballooning of the rectum has been said to be a sign of stricture of the colon. On introducing the finger into the anus in a case in which this condition exists, the bowel will be found to be empty and the rectum so dilated that the finger can at first scarcely reach the limits of its walls. The precise cause of the curious condition has not yet been defined. It evidently concerns the innervation of the bowel. Ballooning of the rectum is often met with in stricture of the colon. It is, however, not diagnostic.—Treves, "*System of Surgery*," page 642.

Obstruction of the Small Intestine.—This most usually takes an acute form. The pain is very intense: vomiting is early copious, persistent, and apt soon to become—on an average about the fifth day—stercoraceous. Meteorism appears comparatively late and is seldom of high grade.

Direction of Pressure in Reducing Hernia.—In a non-pendulous umbilical rupture the pressure is directed backward; in an oblique inguinal hernia upward, outward, and backward; in a large femoral rupture downward, then backward, and a little upward. There is no need to raise the buttocks or to flex and adduct the thigh. The former posture is supposed to allow gravity to assist the surgeon's efforts, and the latter to effect a relaxation of the tissues about the hernial opening. It has, however, been pointed out by many that the taxis is more readily applied when the margins of the opening are not fully relaxed. The flexion and adduction of the thigh are certainly quite useless in dealing with inguinal hernia, but the position appears to be occasionally of assistance in reducing femoral ruptures.—Treves.

Protection against Infection.—A series of experiments has been made which confirmed the opinion of Dr. Billroth that granulation tissue affords an excellent protection against infection. Granulating wounds in various animals were inoculated with different infectious material, and it was found that when the wounds were only two days old no infection occurred. He believes that the cell layers from the granulations form an impermeable protective wall for the open lymph and blood paths from the wound. The exudation from the granulating surface then washes away mechanically the bacteria, which are at last removed with the dressings. The writer is of the opinion that the bactericidal action of the juice from the granulating area and phagocytosis play an entirely secondary rôle. Therefore a practical point of importance is that the slightest abrasion of the granulations may give ingress to bacteria.—Noitzell.

Intussusception.—There are four varieties of intussusception: 1. Enteric: 2, colic: 3, ileo-cæcal: 4, ileocolic. The enteric involves the small intestine and especially the lower jejunum and ileum. It is usually quite short. The colic may be found in any part of the colon, but is most common in the descending colon and sigmoid flexure. It also seldom attains great length. In the ileo-cæcal invagination the ileum and cæcum pass into the colon preceded by the ileocæcal valve, which forms the apex or free extremity of the intussusceptum. This form may attain great size, so that the valve may reach the anus and project beyond it. In the ileo-colic form the end of the ileum is prolapsed through the ileo-cæcal valve. The valve and the cæcum remain, for a while at least, unmoved, and the prolapsed ileum always forms the apex of the intussusception. Out of one hundred cases of intussusception about forty-four will be ileo-cæcal, thirty enteric, eighteen colic, and eight ileo-colic.—Frederick Treves, "*System of Surgery*," page 634.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 29, 1898.

THE NEURON.

IN the old, old days of medicine, some ten or twelve years ago, there were nerve cells and nerve fibres, and these joined in various ways were enough for the Acadian needs of those pre-neuronic times. But in the early eighties there were many startling discoveries made about the structure and relations of the nerve cell and fibre. The latter was shown to be an integral part and process of the former. The nerve fibre was no longer a thing of itself, but simply a long and tenuous branch of the cell body, living or dying just as this latter directed, and as dependent upon it as the branch upon the trunk or the proboscis upon the head. This union of cell and fibre in one nervous unit was recognized and accepted by anatomists for several years, but a concept is made clearer by receiving a good name, and in 1891 Professor Waldeyer called this unit a neuron, from the Greek word νευρόν. Along with the demonstration of this unity of cell and fibre, other equally important facts were observed. Through the influence of Gerlach, it had been generally believed that the nerve cell sent off fine protoplasmic processes, which mingled in a rich network, and that the fibres and processes of other cells penetrated and united with this, so that the protoplasm of all nerve cells was joined in one complicated *continuum*. If we should begin to mention names, there would be no end to our exposition; so we shall only say that through the labors of His, Forel, Cajal, and others, it was shown that Gerlach's ideas were false. The nerve cell does send off many fine processes (which enrich our nomenclature with the name of dendrites), but these all branch and split up to end in free extremities, never uniting with other processes or fibres of other cells. It was also found that the nerve or axis-cylinder process leaves the cell body, takes on a myelin sheath, and gives off as it passes along little side branches, which may run a long distance and are called the "nerve collaterals." The fibre itself and also these collaterals finally split up and end in freely branching tufts of fine fibrils, called the "end tufts" of the nerves. These end tufts lie close to some nerve cell, and mingle their fibres with the "dendrites" of this cell; but they never unite anatomically with them. They simply touch them. Everywhere we find that each neuron is an anatomical republic of its own, though physiologically the contact relations are so sensitive that the slightest impulse flows over from one neuron to another, so that disorders or disarrangements of this contact cause changes in the functional activity of the nerves.

The neuron is divided, like many other important things, into three parts: 1, the cell body and its dendrites; 2, the axis cylinder with its nerve continuation (forming the neuraxon), and collaterals; 3, the end tufts.

The neurons as thus composed make up the great mass of the nerve centres and of the peripheral ganglia, with their outgoing fibres. Some of these neurons are extraordinary in the length and range of their axis-cylinder processes. Thus the neurons which are found in the motor areas of the cortex of the brain send off axis-cylinder processes which reach down as far as the anterior horns of the lumbar and sacral portions of the spinal cord. Such nerve units are therefore, although microscopical in size, over two feet in actual length. Other neurons have very much shorter processes, which soon break up into terminal filaments, and have mainly the function of connecting the different internal portions of the cerebro-spinal axis.

Physiological speculation has not lost time in interpreting the meaning and function of all these different parts. The dendrites were thought by Golgi to be purely nutritive organs, but it is more generally believed now that they carry nerve impulses from the end brushes of distant neurons to the cell body. The axis cylinder is known, in most cases at least, to carry impulses away from the cell body. It is cellulifugal, while the dendrites are cellulipetal.

Ingenious applications of the neuron doctrine (for it is no longer a theory) to the phenomena of fatigue, of sleep, hypnotism, hysteria, and various other nervous and psychic states have been made. If by cellular contraction from fatigue the end tufts of the neuraxons touch less perfectly the dendrites of the next series of cells, the nerve impulses are not so easily transmitted, and consciousness is lessened or more painful, and sleep or feelings of fatigue and incapacity for attention are felt.

New words may be coined with the strictest regard to etymology and orthoepy, but they become part of language through certain inexorable laws, against which the neuronymist struggles in vain. Desperate protests have been registered against the word neuron. Kölliker prefers neurodendron; Kauber, neura; Baker, neure; Schaefer, nerve cell; and Wilder holds that neuron is the cerebro-spinal axis. But in nearly all current and standard literature—French, German, English, American, Italian, Spanish—the word is continually used as first introduced by Waldeyer. And it has at last reached a general dictionary, The Standard, with the Waldeyer spelling and meaning. Even the spelling has been trifled with, and one or two of the younger American anatomists have patched on a terminal "e," making it neurone. But it has been neuron for six years, it stands thus in all American and English literature, and is very likely to remain as spelled in the German way by Professor Waldeyer.

We may say, in conclusion, that although the term was used and described in a text-book of nervous diseases, published in 1892, it is not found in any modern medical dictionary (even the new Sydenham's) which we have been able to consult. The word neuron is found, to be sure, but it is defined as "the nerve," "the cerebro-spinal axis," or "the nervous part of the eye of the arthropod." But this is no longer correct. Neuron was practically never used in the above meanings. It now signifies to all alert minds the nerve unit, and the lexicographer, no longer *æternum meditans decus* of his authority, must adjust himself to the situation.

LEGISLATION AGAINST MEDICAL-CHARITY ABUSES.

Chapter 546 of the general laws of the State of New York provides that the State board of charities shall visit, inspect, and maintain a general supervision of all institutions, societies, or associations which are of a charitable, eleemosynary, correctional, or reformatory character, whether State or municipal, incorporated or not incorporated; shall approve or disapprove the organization and incorporation of all such institutions; shall inquire into their management, and shall establish rules for the reception of inmates, investigate the condition of the poor seeking public aid, and advise measures for their relief. The purpose of the law, in other words, is "by specifically defined action to exercise such a control and influence over the charitable activities of the State, both public and private, as will serve to raise them to a high plane of usefulness, honor, and dignity."

These powers, except to a limited degree, have never been exercised in connection with free medical dispensaries, nor has the exact status of these institutions in the eye of the law ever been clearly defined. The enormous increase of dispensary abuse has excited well-founded alarm, not only on the part of the physician, who is compelled to stand idly by and see his daily bread filched from him under the cloak of charity, but also of the sociologist, who is aware of the direct menace to the underlying principles of economics which is conveyed by universal encouragement of the evil. When the number of persons applying for and receiving free medical and surgical treatment at the dispensaries of a city bears a relation of 49.7 per cent. to the entire population, as was the case in New York last year, it would serve as an alarming commentary on the progress and wealth of the community if the figures even approximately represented the number of applicants who were in any measure worthy of the charity bestowed. On the contrary, it has been conservatively estimated, by those competent to judge, that fully seventy per cent. of these persons were abundantly able to pay a physician at least a moderate fee for his services, and, this being the case, it is evident that the time has come when the condition of affairs must be looked squarely in the face and heroic measures taken to bring about reform.

To this end the Medical Society of the County of New York and other medical societies have caused a bill to be introduced in the legislature during the present week, providing for an amendment to the State charities law of 1896. This bill clearly defines a dispensary, and provides that all such institutions shall be placed under the control of the State board of charities. All dispensaries must obtain a license from the board under which to conduct their operations, and the board is empowered to refuse such licenses, or, if granted, to revoke them in case the rules and regulations which the bill authorizes it to make are not complied with. No dispensary shall be conducted in any drugstore or tenement house, and violation of the provisions of the act or of the rules and regulations of the board is made punishable by a fine of not less than $10 and not more than $250. October 1, 1898, is the date specified for the act to take effect.

While many undoubtedly think that it is unwise and perhaps unnecessary to resort to legislative enactment for the suppression of medical-charity abuses, it must be remembered that since 1870, when the percentage of the city's population receiving free medical treatment at the dispensaries amounted only to 1.5 per cent., every combined effort to control it by other means has resulted in complete and unconditional failure. The present bill perhaps has its faults, but if it becomes a law experience with its workings will point out the best method of instituting improvements. Every medical man in the State should give it his hearty support.

THE HEALTH-BOARD BILL.

Our matutinal coffee is being daily seasoned with scare-head paragraphs in the morning journals, referring to the bill recently introduced in the legislature by the County Medical Society. As a rule, the statements made concerning it are highly flavored with error, although some of them appear to indicate the source from which they originated. Is this clamor on the part of some minor officials of the health board actuated solely by a desire for the public weal, or is it from fear that if the bill should become law their occupation would be gone? When the matters which led up to the preparation of this bill were last spring under discussion before the society, not a single voice was raised in opposition to the impending condemnation of the health board. Even the health commissioner himself, though present, failed to say a word in defence of the board. When the president of the society, in November, condemned the arbitrary and improper procedures of the board, he was applauded to the echo. When, a month later, the committee of five presented its report, including this new bill, it was adopted unanimously; and another month later, at the meeting held last Monday, there was ample opportunity for any one not pleased with the bill to state his objections, yet no one saw fit to do so. Why, we ask, why did not the sanitary officials avail themselves of these ample opportunities to defend their course before the proper tribunal, rather than at the last moment deluge the public with their complaints?

A LITTLE TOO PREVIOUS.

THE *Philadelphia Medical Journal* speaks editorially as follows: "Of the wisdom of requiring cases of tuberculosis to be reported to the board of health, better evidence could not be asked for than that furnished by a recent report of the board of health of New York City, showing a positive and considerable reduction in the mortality from tuberculous disease in that city since notification of such cases has been made obligatory." This would be very well, except that it is not quite in accord with the facts. It is true that in January a year ago the health board did promulgate an order requiring physicians to report all cases of tuberculosis. The order, however, excited much indignation in the profession, and the County Medical Society unanimously adopted the following resolution: "That in the judgment of this society the recent edict of the health department in relation to the compulsory reporting of cases of tuberculosis is unnecessary, inexpedient, and unwise." It is quite within bounds to say that the ordinance referred to has been honored more in the breach than in the observance; and that if there has been a diminution in the mortality from tuberculosis it is not due to the causes assigned by our contemporary. It concludes: "Let the good work go on." What good work?

News of the Week.

The Vermont State Board of Health has recently established a bacteriological laboratory in which bacteriological diagnoses will be made free of charge for physicians of that State. The laboratory will be opened for this branch of its work on February 1st.

Health-Board Assignments in Queens.—Dr. S. McCallum has been appointed head of the sanitary department of the health board of Queens, and Dr. Charles H. Steinsock has been put in charge of the contagious-disease department in the same borough.

Albany Medical College Alumni Dinner.—The third annual banquet of the Albany Medical College Alumni Association was held at Hotel Savoy, January 20th. The president, Dr. Horace Tracy Hanks, acted as toastmaster, and the following invited guests responded to impromptu toasts: Rev. Dr. A. V. V. Raymond, president of Union University; Rev. George Alexander, president of Union Alumni Association; Rev. W. C. Bitting, Hon. Charles M. Earle, Capt. Arthur Murray, U. S. A., and Drs. George F. Shrady, J. M. Mosher, T. D. Crothers, and H. B. Maben.

The Obstetrical Society of Cincinnati.—At the annual meeting of this society the following officers were elected: *President*, Dr. E. S. McKee; *Vice-President*, Dr. W. D. Porter; *Recording Secretary*, Dr. William Gillespie; *Corresponding Secretary*, Dr. M. A. Tate; *Treasurer*, Dr. George E. Jones; *Librarian*, Dr. C. L. Bomisfield.

The New York Medical League.—At the annual election of the New York Medical League, held on January 14th, the following officers were chosen for the ensuing year: *President*, Dr. Joseph E. Janvrin; *Vice-President*, Dr. Frederick R. Sturgis; *Recording Secretary*, Dr. John C. Schminke; *Corresponding Secretary*, Dr. Douglas H. Stewart; *Treasurer*, Dr. E. Eliot Harris; *Trustees*, Drs. Frederick H. Wiggin, E. J. Gallagher, and S. Kennedy; *Finance Committee*, Dr. W. H. Weston; *Members of Executive Committee*, Drs. J. Smith Peterson, Joseph E. Messenger, George D. McGawran, and Wickes Washburn; *Delegates*, Drs. Adolph Rupp, Heinrich Stern, and Joseph H. Byrne.

Decrease of Drunkenness in Ontario.—The license inspector of Ontario, Canada, has recently made a report in which he presents a number of comparative statistics, showing an apparent decrease in the consumption of alcoholic liquors in that province. In 1894–95, the number of licenses was 3,873; in 1895–96, the number was 3,801; and in 1896–97, 3,653. In 1894–95 the fines collected amounted to $17,243.46; in 1895–96, $16,979; in 1896–97, $14,457.01. In 1889 the number of commitments for drunkenness was 4,789; in 1890, 4,573; in 1891, 3,614; in 1892, 2,736; in 1893, 2,625; in 1894, 2,274; in 1895, 2,237; in 1896, 1,907; in 1897, 1,716.

Radical Prophylactic Measures against Rabies.—It is said that, in consequence of a death from hydrophobia in Pisek, Bohemia, the local authorities ordered every dog in the town to be killed.

Small-Pox in Cuba.—Thanks to the insanitary conditions which have prevailed in Cuba from its first settlement by the Spaniards, the island, and especially Havana, has always been a centre of deadly disease. For many years small-pox and yellow fever have been endemic in Havana and the larger cities, the former prevailing with special virulence in the colder months and the latter in the rainy season. The sanitary inspector of the United States Marine Hospital service stationed in Havana reports to the supervising surgeon-general that deaths from small-pox are now increasing in number as those from yellow fever grow less. He says that during the week ending January 14th only four cases of yellow fever resulted fatally in Havana, three of them being in the military hospital. Deaths from small-pox, however, have greatly increased, and the report predicts that the disease will spread rapidly during the next few weeks.

Antitoxin of Hog Cholera.—The chief of the bureau of animal industry in Washington has submitted a report upon the experiments made in the treatment of hog cholera with antitoxin. The serum is obtained from horses and cattle which have been inoculated with the hog-cholera virus. It was tested last fall on several herds of swine in Iowa. Out of 244 animals treated, of which 86 were already sick, only 39 died. Consequently 82.86 per cent. of the animals in these herds were saved, while about 85 per cent. of untreated herds died. The secretary of agriculture purposes to ask Congress for an appropriation which will enable the department to furnish two million doses of the serum for distribution to the farmers

during the coming year. We cannot see why the department of agriculture should go into the antitoxin business when there are enough competent persons in the country who would be glad to manufacture and sell the serum at a reasonable price. It has no more business to go into the manufacturing business than has the New York board of health.

The Late Dr. O'Dwyer.—At the recent meeting of the Medical Society of St. John, N. B., Canada, the following was adopted:

"*Resolved*, That this society has learned with profound regret and sorrow of the death of Dr. Joseph O'Dwyer, of New York, at an age at which we might be led to expect from a man of his character and accomplishments still greater achievements in the domain of science.

"That in Dr. O'Dwyer's death the profession in America has lost one of its brightest ornaments and one of its scientific heroes; who, by his steadfastness of purpose and persevering labor, initiated, demonstrated, and popularized the procedure of intubation of the larynx in diphtheritic croup, a procedure which has been phenomenally successful in rescuing from certain death tens of thousands of patients annually.

"That in the great galaxy of brilliant names which this closing century presents to the century about to dawn there is none deserving of a more honored place than that of Joseph O'Dwyer. And further

"*Resolved*, That this society desires to convey to his family, the immediate circle of his friends, and to the profession in New York, its sincere and heartfelt sympathy in the great loss they have sustained in his early removal from a sphere of great usefulness and activity."

The medical board of St. Vincent's Hospital, at a special meeting held January 8, 1898, caused the following minute, relating to the death of Dr. Joseph O'Dwyer, one of the physicians of the hospital, to be entered on its records:

"The members of the medical board of St. Vincent's Hospital have learned of the death of their colleague, Dr. Joseph O'Dwyer, with profound regret. He was faithful and conscientious in the performance of every duty devolving upon him as a medical officer of the hospital, while the scientific spirit which governed and directed his service in the care and treatment of the sick contributed both to the welfare of the patients and to the elevation of the standard of medical practice of the hospital. Dr. O'Dwyer was a most helpful companion and friend. In the field of scientific medicine he had gained a world-wide reputation by his discovery of a method of intubation in laryngeal stenosis, which has resulted in an immense saving of child life in diphtheria. Though yet in middle life, Dr. O'Dwyer had already won the highest prizes of human ambition, viz., the gratitude of the sick, the love and respect of his associates, and an exalted rank in his profession.

"C. J. MacGuire,
"P. S. Morrow,
"Stephen Smith,
"*Committee.*"

The Prevention of Typhoid Fever.—In the article on this subject in the Medical Record of January 15th, the tenth line from the end should read "one-tenth per ten thousand" instead of one per ten thousand.

For the Benefit of Overworked Drug Clerks.—A bill has been introduced in the legislature of this State which is designed to relieve drug clerks in the city of New York from extra long hours of work. The ostensible object of the measure is the prevention of mistakes in mixing wrong drugs, due to mental confusion resulting from overwork. The bill provides that no clerk shall work more than ten hours a day, except on Saturday, when he may work twelve hours. On Sundays and holidays only six hours' work is allowed.

Christian Science and the Law.—A Christian science "doctor" was fined $50 recently in a Kansas City police court for not reporting to the board of health a case of diphtheria in a family in which a ten-year-old child afterward died. The woman had administered Christian science treatment to the child. The case was appealed, but the judgment of the trial tribunal was sustained. In the opinion delivered in affirmation of the judgment of the lower court, the judge said the methods of Christian science in attempting to heal were frequently akin to murder.

Aged Parents.—A woman in Toronto who is over sixty years of age gave birth on January 21st to a baby girl. Her husband, to whom she was married seven years ago, is seventy-eight years of age. The mother has been married twice, and this is her twenty-second child. The day after this, not to be outdone by any foreigner, a woman sixty-five years old, living in Oklahoma, also gave birth to a baby girl. This mother has also a number of other children, ranging in age from thirty-five to forty-five years. Some of the male sex have, as might naturally be supposed, better records than this. A Tyrolese gentleman named Parravicini, is reported to have married at the age of eighty-two years, and to have been the father of seven children, the last of whom was posthumous, his father having died at the age of one hundred and four years. Juba, king of Mauritania, is believed to have died at the age of ninety-one years, leaving a posthumous child.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending January 22, 1898. January 18th.—Surgeon A. G. Cabell ordered home and granted three months' sick leave. January 20th.—Passed Assistant Surgeon A. W. Dunbar, order of January 12th modified; detached from the *Nashville*, and ordered to the *San Francisco* by steamer of January 22d.

A Belligerent Doctor.—A St. Louis physician was recently called upon just at the close of his office hours by a man who had accidentally shot himself in the hand, and asked to have the wound dressed. The physician, who is reported to be somewhat irascible,

and we are inclined to believe it, was preparing to leave his office, and declined to treat the visitor. When the latter insisted, the doctor chased him out of the house with a revolver. The would-be patient then returned with his father, and began to expostulate with the would-not-be surgeon, who rose in his wrath and chased them both down the street with a revolver. The wound was dressed by another physician, and the aggrieved party has got out a warrant for the doctor's arrest.

Telephones for Hospital Patients.—It is stated that telephones are to be placed in the wards of one of the Paris hospitals, within reach of the bedridden patients, so as to enable them to communicate with their friends outside. There will also be an arrangement whereby the telephones may be switched on to a wire connected with a concert hall, so that the performance may be enjoyed by the invalids.

A Proposed Quarantine Station on the Columbia River.—It is stated that, in response to urgent appeals of the Marine Hospital service, a quarantine station will be established at the mouth of the Columbia River, on the Pacific coast. There are at present no facilities on the Columbia River for the proper disinfection of vessels, the detention of suspects, or the treatment of those suffering from infectious diseases.

Hydrotherapy in Vienna. — Appliances for the employment of water in medical treatment have recently been placed in the Austrian military hospitals, and a chair of hydrotherapy is soon to be established in the University of Vienna.

Fire in a Hospital.—The hospital building of the Nursery and Child's Hospital, on Staten Island, caught fire last Saturday night at half-past ten o'clock, but the flames were extinguished before serious damage was done. The children were all removed to another building by the nurses, and none of them, it is thought, will suffer from the exposure.

The Dispensary Abuse.—A remedy for the abuse of medical charity, which has been suggested in Philadelphia, is that treatment at the dispensaries be given only to those bringing from some charitable association a certificate as to their worthiness.

To Prevent a Recurrence of Yellow Fever in the South.—The following suggestions, signed by Drs. J. H. White, of the Marine Hospital service; William Gorenflo, of the Biloxi board of health; and W. T. Bolton, health officer of Harrison County, Miss., have been published and sent to all residents in Harrison County: "1. Open wide to the cold air and sunlight every house on every cold day, not only once, but every cold day from now until March. 2. Hang out of doors all mattresses, pillows, cotton comforters, blankets, and clothing. 3. Unpack and hang out of doors all kinds of clothing, both woollen and cotton, which may be packed away in drawers, trunks, or boxes. 4. Turn over to the disinfecting service all mattresses, pillows, comforters, etc., used in or about the sick-room for any sort of fever during the past summer and fall. 5. Lastly, the mattresses, pillows, and comforters will be disinfected by steam, the other things by formaldehyde gas, and in neither case will anything be damaged. If it be necessary to burn any badly infected mattress, the government will replace the mattress with another of exactly the same quality. No discomfort and no loss to any one will occur."

"La Crónica Medica Mexicana" is a monthly periodical, established July 1st, in the City of Mexico, under the editorial management of Dr. Enrique L. Abogado, with the assistance of Drs. Demetrio Mejía, Manuel Barreiro, and Juan Duque de Estrada. We congratulate the learned editor upon the completion of the first volume, and prophesy a successful career for the *Crónica* if the standard of excellence set in the first numbers is maintained in the future issues of the journal.

The United Hebrew Charities.—A lot on the southeast corner of Second Avenue and Twenty-first Street has been purchased by a gentleman who, it is said, intends to erect a building to serve as a permanent home for the United Hebrew Charities.

The Health of Montclair.—The vital statistics of Montclair, N. J., for the past year show a remarkably low death rate. The deaths registered with the board of health represent a rate for the year of 12.98 per 1,000 on an estimated population of 12,000. The total number of deaths was 161, principally from the following causes: Consumption, 16; diarrhœal diseases of children, 15; pneumonia, 13; asthma, 13; heart disease, 12; marasmus, 6; apoplexy, 6; diphtheria, 6; typhoid fever, 4; scarlet fever, 2. There were 316 births during 1897.

Dr. Arthur B. Duel has been appointed consulting aural surgeon to the Willard Parker and Riverside hospitals in this city.

The Brooklyn Neurological Society.—At the annual meeting of this society, recently held, Dr. A. C. Brush was elected president, and Dr. W. H. Haynes secretary for the ensuing year.

The Ninth International Congress of Hygiene and Demography will be held in Madrid on April 10–17, 1898, under the patronage of the King and the Queen Regent of Spain. A most cordial invitation is extended by the secretary-general of the congress, Dr. Amalio Gimeno, to all physicians, health officers, pharmacists, veterinarians, sanitary engineers, architects, statisticians, and all interested in any of the subjects to be discussed, to prepare papers and attend in person the meetings of the congress. "This is the first time," Dr. Gimeno writes, "that an assembly of such importance as the International Congress of Hygiene and Demography is to be held in Spain, and every one of us is ready to demonstrate that, notwithstanding the political convulsions and wars that for so long a period have mostly absorbed our energies and our wealth, the care of public health and the love of science, as far as the study and acquaintance with every progress are concerned, are in a level with a superior culture, never so well understood as at present."

A Despotic Society.— According to the *Georgia Journal of Medicine and Surgery*, there is a medical society in Savannah, called the Georgia Medical Society, which has a law which requires that every man who purposes practising medicine in Savannah shall, within six months, apply for membership in the society, failing to do which no member shall consult with him; again, failing of election, no member shall consult with him.

Cholera in India.—There is reported to be a recrudescence of cholera in the Bombay presidency, especially in Mandwi, where the inhabitants are seeking safety in flight. There were 54 fresh cases of cholera and 37 deaths there from cholera on December 29th. The total cholera returns for the Bombay presidency during the year are 14,257 cases and 11,882 deaths.

A Chinese Edition of "Gray's Anatomy."—Dr. H. T. Whitney, president of the Medical Missionary Association of China, is engaged in the laborious task of translating "Gray's Anatomy" into Chinese. The undertaking has impressed Dr. Whitney's former associates in the Northern Ohio District Medical Society as one of such magnitude that they have come to his assistance by passing a special resolution congratulating him and wishing him God speed in his work.

The Æsculapian Society of the Wabash Valley is a contemporary of the American Medical Association, having been organized in 1846. Its charter was granted a year later, however, so it dates its foundation from 1847. The semicentennial meeting was held at Paris, Ill., in October last.

Contemplated Consolidation of Medical Colleges.—A mild flirtation is said to be going on in medical circles of Columbus, by which the Ohio State University desires to secure a union of the two local schools, to form a medical department of the State University.

Reorganization of the Graduates of the Charity Hospital Training-School for Nurses.—A union of the various groups of graduates of the training-school at Charity Hospital has been effected under the name of the Graduates' Co-operative Registry of the New York City (Charity Hospital) Training-School for Nurses. The members of the registry have elected the officers of the Charity Hospital Alumni Association as an advisory board.

Yellow-Fever Microbe.—At a meeting of the New Orleans Medical Society, held January 22d, Dr. Paul E. Archinard, bacteriologist of the Louisiana State board of health, made a report of his investigations during the recent yellow-fever epidemic. The experiments were conducted by Dr. Archinard, assisted by Dr. R. S. Woodson, of Johns Hopkins University, and Dr. John J. Archinard. The speaker announced that in a large proportion of the cases examined they had found the germ discovered by Sanarelli. They had also applied Widal's test to yellow fever, with success. By means of this test applied to cases of dengue, they found that in many instances dengue and yellow fever occurred coincidently in the same individual.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Second Annual Meeting, Held in Albany, January 25, 26, and 27, 1898.

SENECA D. POWELL, M.D., OF NEW YORK, PRESIDENT.

First Day—Tuesday, January 25th.

THE meeting was opened with prayer by the REV. CHARLES A. RICHMOND, of Albany.

President's Inaugural Address.—DR. SENECA D. POWELL, of New York City, then delivered the inaugural address. He said that eight hundred and sixty-two candidates had appeared at the licensing examinations during the past year, and six hundred and twenty-seven had been accepted. The average percentage of rejection was twenty-two. The president recommended that better legal safeguards be thrown around the sale of poisons; that the place of meeting of the society remain as hitherto—Albany; and that no change be made in the method of electing the officers of the society.

Report of Committee on Legislation.—The committee, among other things, called attention to the effort made before the last legislature by the New York State Medical Association, to obtain equal recognition with the Medical Society of the State of New York. The committee of the latter society submitted to the legislature a brief, which contained such cogent arguments that the bill in question was permanently pigeonholed.

State Board of Medical Examiners.—DR. M. J. LEWI, in presenting this report, stated that the examinations of the five hundred and forty-five graduates of New York institutions were more satisfactory than those from other schools, in the ratio of two to one. In one case during the year, after proper evidence, the license to practise was revoked.

Change of Districts.—A special committee, having under consideration this matter, reported through DR. WILLIAM BROWNING that it favored the adoption of the present judicial districts instead of the obsolete senatorial districts of equal number. This measure, which was adopted by the society, involves the division of the fifth and eighth districts.

Place of Meeting.—After a long discussion on the advisability of having the society meet alternately in New York City, Buffalo, and Albany, the proposal to make this change in the bylaws was rejected.

Ear Manifestations in General Disease.—DR. WENDELL C. PHILLIPS, of New York, reported several cases illustrating the subject of the paper. He called attention to the fact that at the present time several life-insurance companies refused all cases of chronic suppuration of the ear, or else accepted them only after an expert had expressed the opinion that there was no probability of brain complications. The reader of the paper stated that ear symptoms produced by traumatism were often very puzzling. Otalgia was very common in both suppurative and follicular tonsillitis. As a rule, in such cases there was no inflammation of the middle ear. The author then considered, by reference to statistics, the important relation between deaf-mutism and adenoids of the vault of the pharynx. The paper closed with an earnest plea for more attention, on the part of the general practitioner, to the ear complications so liable to arise in the course of the acute exanthemata, particularly scarlet fever.

Cases of Acute Non-Diphtheritic Inflammation of the Larynx Requiring the Prolonged Retention of the Intubation Tube.—Dr. John O. Roe, of Rochester, reported two very interesting cases of this kind, in one of which the tube was retained for six and one-half weeks, and in the other for nine weeks. He stated that the late Dr. O'Dwyer had reported two of these curious cases, in one of which the period of retention had been ten months, and in the other fifteen months. In one of his own cases, the tube had been repeatedly coughed up, and this, too, in spite of the fact that the tube was somewhat larger than that intended for the age of the patient and that the tube had been skilfully made after the latest approved O'Dwyer pattern.

Report of a Case of Unusual Contraction of the Visual Field and Disorder of the Color Sense Following an Injury.—Dr. T. F. C. Van Allen, of Albany, reported a case of this kind, occurring in a painter, thirty-six years of age, who had been injured by a scaffold falling upon him. There was a scalp wound over the left upper and posterior part of the temporal region, but no evidence of fracture of the skull. Five weeks after the injury he discovered a blurring of vision, and some time afterward an inability to distinguish between certain colors. Examination of the eye showed, in addition to great contraction of the visual field, marked disturbance of the color field. At present the man experiences great difficulty in matching certain shades of green, except when viewed in a certain light.

The Railway Surgeon and His Work.—Dr. C. B. Herrick, of Troy, read this paper. He said that of the working force on the railroads of this country or more than one hundred a day were injured. The injuries differ from those received elsewhere in their extent and severity, the two most important determining factors being prodigious weight and high velocity. A slowly moving train crushes a limb as though it had been squeezed in a vice, but allows the proximal portions to retain their vitality. On the other hand, a high-speed train produces a form of injury which is often very misleading in its appearances. Owing to the elasticity of a limb, it is possible for a train to run over it and crush the deeper tissues without leaving any external mark. In railway surgery conservatism is chiefly practised in injuries of the upper extermity, particularly of the hand. Amputations through joints are not considered desirable, because the leaving of any part of a joint interferes with the proper application of an artificial limb. At present there are about six thousand railway surgeons, who, in addition to treating the injured, have done much in the way of establishing railway hospitals, training the employees in "first aid to the injured," and in improving the sanitary condition of railway conveyances.

The Rivals of the Physician in Practice.—Dr. Reynold W. Wilcox read a paper with this title, in which he spoke of the efforts made by certain "docs" to practise medicine, regardless of their qualifications. Among these rivals were the trained nurses who prescribe for patients, the nurses who consider themselves competent to treat heart disease by the Schott method, the chiropodists, the opticians, and the barbers. He had recently met with a case in which an obscure condition of urethral irritation and strangury had been traced to the use of a hair tonic that had been prescribed by a barber.

What Shall the State and Country do for the Consumptive?—Dr. John H. Pryor, of Buffalo, in a paper on this subject, stated that thirteen thousand consumptives die annually in this State, largely because misguided philanthropy had attended to the incurable cases, to the neglect of the many poor persons who have the disease only in its incipiency. The establishment of a proper home for such persons in the Adirondacks would probably be the means of saving twenty-five to thirty-five per cent.

The subject matter of the paper was referred to the committee on hygiene.

The Advantages of State Control in Medicine.—Dr. William Warren Potter, of Buffalo, read this paper. He urged the advantages that would accrue from having a uniform standard of requirements in all the States. Such a standard should embrace the triad of preliminary education, medical collegiate training, and State examinations for license. A national clearing-house, made up of representatives from the different States, could pass upon the diplomas of those who wish to change their residence from one State to another. The graduates of medical schools, as well as their teachers, now quite generally commend the work done under the "practice law."

Anæmia.—Dr. R. C. M. Page, of New York, read the paper. He defined anæmia as a deficiency in the number of the red blood corpuscles, and leukæmia as a condition in which there is also an increase in the number of the white corpuscles. He thought the term "chlorosis" should be restricted to that condition found in young girls in whom there is amenorrhœa or deranged menstruation, for it is not always associated with anæmia. Another variety of anæmia, and one not very commonly recognized, is that due to a relaxed condition of the abdominal walls and viscera, and a consequent increased activity of the spleen. Experience had taught him that when an anæmic woman does not readily respond to the usual treatment the spleen will almost invariably be found sufficiently enlarged to produce an area of dulness from the ninth to the eleventh ribs. His treatment consists in the internal use of iron, iodide of potassium, and arsenic, and the external daily use over the spleen of an ointment of iodide of potassium—two grains to the ounce.

The Overweighted Knee.—Dr. W. S. Ely, of Rochester, in a paper with this title, called attention to a small class of cases in which the function of the knee was affected as a result of the heavy body weight to be sustained. Knee strain can be produced just as much by obesity as by occupations requiring the lifting of heavy weights. The most troublesome cases to treat are those in which the muscles are lax, and the adipose tissue is overdeveloped.

Expert Medical Testimony.—Dr. J. B. Ransom, of Dannemora, presented a paper on this subject. He thought it was time that the medical profession took more than a languid interest in this topic, in view of a recent decision in an Illinois court (cited on the authority of Attorney-General Aitken) that the medical expert witness is in no way different from the ordinary witness. Dr. Ransom said that he had personally contested this much-vexed question three times in the supreme court of New York State, but had been supported by the court in only one of these instances. He said that it was now generally agreed that it would be better to have medical experts appointed by the trial judge for each case, and also to have some standard of qualification. It had been suggested that a certificate of qualification should be issued by the board of regents, after the applicant had passed a satisfactory examination and had practised his specialty not less than five years. In this proposed scheme of legislation, the people are protected by the appointment of experts by the court; the accused is protected by an impartial board of experts who pass upon hypothetical questions; and the medical profession is protected by the qualifications demanded of the experts.

Dr. Evarts M. Morrell, of New York, urged medical experts to insist upon proper remuneration for their services.

Dr. A. Walter Suiter, of Herkimer, described his experience in committee work during the past few years, relative to this subject. He objected to the court appointing the experts, for judges are but human and are open to the influences felt by other persons.

Dr. Landon Carter Gray expressed the same opinion regarding appointments by the judiciary, but he thought, with the safeguard of having the selections made from a list furnished by the board of regents, a good beginning in the reform movement could be made.

Dr. Edward B. Angell, of Rochester, said that this subject had recently been very fully discussed at Buffalo by a number of learned members of the legal profession, yet the consensus of opinion among them seemed to be that no plan yet proposed is feasible. Moreover, any such effort at reform would meet with strong opposition from a large class of lawyers who see in it diminished opportunities to rescue their clients from the clutches of the law.

Dr. Ransom replied that physicians should take the initiative in this matter, if the legal profession did not feel disposed to co-operate.

A Contribution to the Study of Melancholia, with a Report of the Examination of the Blood in Fifty-Seven Cases.—Dr. R. C. Loveland, of Clifton Springs, contributed this paper. His observations differed from most of those hitherto reported, in that they were made during the early stages of the disease. Attention was directed to the fact that the urine was often in a state of high concentration, suggesting that other secretions of the body were in a similar condition. In his observations the highest hæmoglobin percentage was one hundred and twenty by the Fleischmann instrument, and one hundred and thirty-five by the Gowers instrument. The lowest readings were seventy-five and ninety per cent. respectively. He stated that one observer, who had examined the blood in thirty-five cases of melancholia, had reported a deficiency in the hæmoglobin and of the hæmatocytes, but he had never met with melancholia in cases of anæmia. In the treatment of melancholia, elimination should be promoted in every possible way, not forgetting the solvent power of water when partaken of freely. Out of the fifty cases of melancholia under his treatment for a long time, thirty-five had ended in recovery, eight had been improved, and only two had remained unimproved. He attributed his success largely to the great attention paid to the proper feeding of those patients.

Dr. Russell said he would ascribe the success achieved in these cases to the careful selection of the food rather than to the quantity taken; the common fault was to give an excess of food as compared with the amount of exercise taken.

Dr. L. D. Bulkley, of New York, believed the secret of this success was to be found in the author's expression, that he takes a careful "inventory" of his patient, and does not neglect the minor details.

Dr. Edward D. Fisher, of New York, expressed the belief that melancholia, as well as other forms of mental disease, were greatly benefited by excessive feeding.

Dr. Loveland replied that both quality and quantity of food were important.

The Cold-Water Treatment of Typhoid Fever in Private Practice.—Dr. John T. Wheeler, of Chatham, read a paper on this subject. He said that scientific proof was not lacking of the value of the Brand bath treatment of typhoid fever, but human nature, which must always be reckoned with in private practice, had decided that the method was too heroic. For this reason the treatment had had but a limited sphere in private life, and other so-called "milder" methods had been used instead. Dr. Wheeler said that in his twenty-three years of practice he had treated almost all of his cases of typhoid fever—over one hundred and twenty in all—by cold sponge baths. Although he had passed through several severe epidemic of the disease, and the average type had been quite severe, he had lost only one case. His custom was to order the baths every two hours during the day in all cases in which the diagnosis was reasonably clear, and the symptoms—fever and other manifestations—were fairly active. The duration of the bath varied from fifteen to forty-five minutes in most cases, depending upon the severity of the disease, but in the severest forms the baths were used almost continuously for hours at a time. In brief his rule was to meet obstinacy of symptoms by persistency of treatment. The body temperature alone was not looked upon as the guide to the use of these baths, but rather the urgency of all of the symptoms. The temperature of the bath was a compromise, in which the feelings of the patient, his strength, the severity of the symptoms, and the duration of the bath were the determining factors. It would often be found that water at a temperature which was comfortable to the patient met all requirements If his circulation was feeble, a good preliminary measure was friction of the body surface. This made the bath more acceptable, and did not cause the temperature to rise. Intestinal hemorrhage was a contraindication to the use of the baths, pneumonia was not necessarily so, and bronchitis was not a contraindication at all. This bath treatment should be resorted to very early in the disease, for it should be remembered that the crisis in typhoid fever was not really in the third or fourth week, but in the first week.

Dr. Russell heartily indorsed this treatment, and said that it was very gratifying to see the severe symptoms of typhoid fever abate under this simple method of nature, when they had previously resisted the most scientific drug treatment. The extra trouble and labor involved in the bath treatment were more than counterbalanced by the superior results achieved.

Vagaries and Wanderings of Gall Stones, with Clinical Reports.—Dr. Henry L. Elsner, of Syracuse, presented a communication with this title, in which he related the clinical histories of several curious cases of this kind. In one case the whole clinical picture at first had been that of carcinoma of the pylorus. Finally, a gall stone, measuring thirteen centimetres in circumference and weighing twenty-three grams, was discharged. About eleven days after this event the patient developed symptoms simulating those of an acute indigestion, but the attack culminated in the discharge of a smaller stone. In another case a large gall stone ulcerated through the gall bladder and wandered into the retroperitoneal space, finally lodging behind the pancreas, and giving rise to symptoms of cancer of the pancreas. In still another case in which there was a history of biliary colic and abscess over the tumor, six hundred and one small stones were found in the gall bladder, having a total weight of four hundred and seventy grains. In conclusion, the speaker expressed the opinion that the persistence of symptoms of gall stones should be an indication for an immediate consultation between the physician and the surgeon. As in appendicitis, this practice would soon result in a lowered mortality.

Dr. Loveland mentioned some of the difficulties met with in making a diagnosis of gall stones, and heartily indorsed the opinion that surgical aid should be called in at an early date.

Dr. F. W. Sears, of Syracuse, narrated an interesting and singular case in which a woman, seven months pregnant, developed albuminuria, anasarca, jaundice, and gall-stone colic, and then miscarried. She was delivered of a dead child, and the amniotic fluid was deeply tinged with bile.

Dr. Willis G. Macdonald, of Albany, called attention to the danger of delaying surgical interference

in these cases of gall stones until a condition of cholæmia had become established.

Paralysis: Its Forms, Prognosis, and Treatment.—Dr. Edward D. Fisher, of New York, read this paper. He said that the simplest classification is that based upon the location of the lesion causing the paralysis. There are, according to this view, four forms, viz.: (1) Cerebral paralysis; (2) spinal paralysis; (3) peripheral nerve paralysis; and (4) intramuscular paralysis. Cerebral paralysis is most commonly the result of meningeal or intracerebral hemorrhage, thrombosis, syphilitic endarteritis, and tumors. The distribution is characteristic, being in the majority of cases unilateral. Another marked condition is the absence of any atrophy of the muscle at the time. There is no change in the electrical reaction. The more common cases found in the second class are acute and chronic inflammations, hemorrhage, and compressions, as in cases of spinal fracture and dislocation. The special characteristics of this class are the atrophy and flaccidity of the muscles, the loss of reflexes and response to the faradic current, the reaction of degeneration with the galvanic current in acute diseases, and decreased response to both currents in the more chronic cases. There is also an absence of sensory disturbances. Poliomyelitis and progressive muscular atrophy of the spinal type are the best examples of this class. The common causes of the third class are blood states, such as rheumatism and gout, or specific diseases, such as typhoid fever, diphtheria, and malaria. Additional causes are lead and mercurial poisoning and injuries to nerves. The paralysis is of the spinal type, but it is usually associated with marked sensory symptoms, especially in the acute disorders. There is always great tenderness along the affected nerves and the muscles supplied by these nerves, and the general sensation is also usually disturbed. The fourth class is also known under the name "muscular dystrophy." The cause is obscure, but apparently has its seat in some elemental developmental defect. It might with propriety be designated "hereditary progressive muscular atrophy." The paralysis is of the spinal type. The prognosis is on the whole unfavorable, for nerve cells once destroyed are not replaced. Regarding treatment Dr. Fisher said that much good could be accomplished by massage, galvanism, and hydrotherapy. In poliomyelitis the paralyzed muscles should be treated by massage and electricity for at least a year or more, and apparatus employed for the exercise of the muscles. When orthopædic apparatus must be worn, it should be very light, so as not to retard but rather to aid efforts at locomotion.

Dr. E. B. Angell said that in estimating the prognosis in a case of sudden paralysis due to cerebral hemorrhage the thermometer would be found exceedingly useful. If the rectal temperature rises steadily after the onset of the attack, the prognosis may be stated to be absolutely hopeless; if, however, the temperature rises in the first few hours to about 102° F., and then begins to go down, there is a fair prospect of recovery, no matter how deep the coma may appear to be. Operative surgery holds out considerable encouragement in cases of meningeal hemorrhage.

The Relation of Bacteria to the Normal Alimentary Canal.—Dr. Herbert U. Williams, of Buffalo, read this paper. He stated that at times bacteria are found which are able to digest all the different kinds of food, but it has not been proved that they are normally inhabitants of the alimentary canal. The only fairly constant organism is the colon bacillus, which has no important digestive action on the usual food stuffs; but its constant presence during health is at present inexplicable, although it suggests some unknown but useful relation.

The X-Ray in Medicine and Surgery.—This was the general subject for consideration at the evening session.

Technique and Apparatus.—Dr. Samuel Lloyd discussed this phase of the subject. He said there were three different means of generating the *x*-ray, viz., (1) the Tesla tube, (2) the static machine, and (3) the induction coil. The Tesla coil had been used by very few surgeons. The static apparatus gave excellent results, but the apparatus was more or less uncertain in its action. The induction coil was very noisy in its action, but the most reliable means. A new vacuum tube was exhibited, the invention of Dr. Rawlins, of Boston, which is so constructed that a current of water circulating about the anodal end of the tube prevents excessive heating. The intensity of the *x*-ray must be adapted to the special case to be examined, if the best results were to be obtained.

The X-Ray in Medicine.—Dr. Francis H. Williams, of Boston, spoke on this part of the subject. For medical purposes he said the *x*-ray must be elaborate and of the very best quality. The harmful effects of these rays are entirely avoidable. Many excellent radiographs and charts were exhibited in order to give an adequate conception of the possibilities in this direction. Fluoroscopic examination of the chest shows (1) the presence of dark areas in tuberculosis, pneumonia, carcinoma, gangrene of the lung, infarction, pleurisy, empyema, etc.; (2) the occurrence of abnormal brightness in emphysema and pneumothorax; and (3) restriction of the excursions of the diaphragm and the altered position of the latter. In pneumonia the affected areas can be readily recognized through the fluoroscope. In young people especially emphysema is apt to be overlooked by auscultation and percussion, but it is easily detected by the fluoroscope. Within certain limits the brightness of the lungs varies in health. For example, it is lighter during deep inspiration than on deep expiration, probably because of varying quantity of blood in the lungs.

Dr. Arthur L. Fisk, of New York, then exhibited a large number of lantern views showing the aid given to surgery by the *x*-rays.

Dr. William Hailes, of Albany, exhibited a collection of wonderfully beautiful microscopical specimens, illustrative of the teaching-possibilities of microscopic projection.

Second Day—Wednesday, January 26th.

The Hygienic Management of Dairies.—Dr. E. F. Brush, of Mount Vernon, read this paper. He spoke of the various ways in which milk may be infected in the dairy, aside from the condition of the cows themselves, and also of the many other sources of contamination. The heating of the milk may destroy bacteria, but it will not eliminate the toxins that may have already formed in the milk. The milk should be in wholesome condition when it reaches the consumer, and not need to be "doctored" by laboratory methods.

The Municipal Control of Milk Supply in Cities and Villages, with Report of Health Regulations.—Dr. W. H. Heath in this paper made a strong plea for supervision of the milk supply by the State board of health as well as by cities. The mode of transporting milk by railroad is defective in many respects. The delivery of milk inside of houses in which there is an infectious disease and the removal of empty milk bottles from these houses should be prohibited and the prohibition rigidly enforced.

The Treatment of Stricture of the Urethra by Continuous Elastic Dilatation.—Dr. R. J. Wilding, of Malone, presented this paper. He said that any method of treating urethral stricture that does not tend

to produce absorption of the abnormal bands about the urethra must necessarily result in many failures. His method of treatment does not confine the patient in bed, and usually allows him to continue his occupation. In brief, the method consists in the successive insertion of soft-rubber catheters and leaving each one in the urethra for twenty-four to forty-eight hours. The catheter should be a few sizes larger than the calibre of stricture. It is stretched over a guide to allow of its introduction, and on the removal of this guide, the catheter resumes its former size and exerts elastic pressure on the stricture. These catheters cause very little irritation and no inflammation. The catheter is of course tied in place, and the distal opening closed with a plug. The usual after-treatment, by the occasional introduction of a steel sound, was recommended.

Some Points in the Technique of the Alexander Operation.—Dr. Herman E. Hayd, of Buffalo, in a paper with this title, advocated the operation which picks up the ligament at the external ring. He laid great stress upon the necessity of saving the knuckle of fat which pops out of the external opening, as he considered this bunch of fat the landmark to the operation. His plan is to cut off the ends of the ligament and transfix the cord through a thick portion, taking care not to draw the suture too tightly in approximating the pillars. He believes that too much traction on the poorly nourished cord is apt to favor suppuration. The speaker objected to all operations which open up the canal, as he was convinced that such a course is not only unnecessary, but complicates the operation and favors the production of hernia.

The Present Status of Vaginal Operations for Diseases of the Pelvic Organs.—Dr. Edwin B. Cragin, of New York, read this paper. He said that he thought the time had arrived for a calm consideration of the utility of vaginal operations. The objections to the vaginal operation are that it is more difficult than the abdominal operation and, in inexperienced hands, is more likely to result in rectal fistula. However, in properly selected cases this operation is followed by less shock, convalescence is smoother, and the mortality is less. Hernia must certainly be a very rare sequela. The question to decide now is, not what operations can be done through the vagina, but what operations are best done by that route. His own opinion was, that with the exception of cases of small ovarian tumors, if the uterus is not to be removed, the abdominal operation is preferable—in other words, except in the case of small ovarian cysts and prolapsed and diseased ovaries needing removal, unilateral disease of the appendages is best dealt with from above. He also preferred the abdominal route for cases of ectopic gestation, except when rupture has taken place some time previously and the hæmatocele has been thoroughly encapsulated. Conservative work upon the appendages is generally better done from above. The operation of vaginal fixation for posterior displacement has been nearly abandoned. In his hands the vaginal operation has proved of great service in cases of pregnancy in which the parturient canal was obstructed by tumors. In three cases of this kind this operation has enabled him to deliver a living child. According to his experience the vaginal operation has proved a great boon in three groups of cases, viz.: (1) Pus cases in which the removal of the uterus and appendages is indicated; (2) cases in which the exudate indicates the necessity for drainage without removal of the organ; and (3) small fibro-myomata. In the matter of technique, Dr. Cragin emphasized the value of morcellation, the Mikulicz drain through the vagina, and the use of ligatures. In conclusion, he expressed the belief that, by reason of the vaginal operation, surgeons are now in a much better position than formerly to treat pelvic disease.

Remote Consequences of Excessive Uterine Hemorrhage.—Dr. W. E. Ford, of Utica, presented this paper. He said that when a laceration extends above the internal os the loss of blood is likely to be large at the time and to continue afterward. The degenerated endothelium often protracts the hemorrhage. As a result of this large blood loss, a neuritis is started up, and furnishes the beginning of the so-called neurasthenia uteri. It is in these cases that trachelorrhaphy fails to cure the nervous symptoms. Amputation of the cervix is a better operation here. The blood count in most of these cases shows no true anæmia. Rarely does the hæmoglobin fall below eighty-five per cent. All lacerations of the cervix which extend up to the internal os should be repaired early, before the development of the neuralgic condition. The author then contrasted the blood counts in these cases with those obtained in young women having delayed or suppressed menstruation, thus emphasizing the statement already made, that there is no true and marked anæmia. Diluents and diuretics seem to do more good than does iron in the way of medication.

The Anatomy and Function of the Pelvic Floor in Women, and the Operation for Repair of Injuries Due to Parturition.—Dr. J. Riddle Goffe, of New York, presented a communication on this subject. He said that while he believed in the function of the perineum he did not believe in the function of the perineal "body." The function of the perineum, according to his view, is entirely passive, and is threefold, viz.: (1) To fill in the anatomical space in that region; (2) to give attachment to one end of the levator ani muscle; and (3) to get out of the way of the advancing head in parturition, and of the fæcal mass in defecation. Under the name "levator ani" he included for purposes of description all the muscles constituting the floor of the female pelvis. This "muscle" is conical, with bony attachments to the outlet of the pelvis, and an insertion into the tendinous centre of the perineum. In parturition, as the head of the child descends on to the pelvic floor, the levator ani lifts the perineum over the face of the child. The same action takes place in defecation, except that in this instance the mass is behind instead of in front. In some cases of forceps delivery rupture of the perineum occurs in the middle line, but in the great majority of cases the rupture takes place a little to one side of the middle line. In his experience such ruptures were produced, not so much by the fœtal head as by the shoulders suddenly catching in the tissues on one side and tearing away the attachment. When this occurs, the transversus perinæi muscles immediately retract into the deeper structures, and in doing so carry the two sides of the levator ani muscle. The portion extending from the tendinous centre to the coccyx being unyielding, it follows that during the act of defecation in cases of ruptured perineum the anterior wall of the rectum is carried downward with the fæcal mass, and the tendency is for it to escape through the vulva. This leads to the formation of a rectocele. In repairing the perineum, it is important, therefore, to get rid of the rectocele, and restore to their normal position the two ends of the transversus perinæi muscles, which in retracting have drawn aside the levator ani muscle. Beginning with the carunculæ at the highest point of the perineum and the highest point of the rectocele, a triangular flap is rapidly removed; then, starting at the top of the rectocele, the two or three sutures are inserted so as to tuck back the rectocele into the vagina. The last suture passes just above the caruncle, sweeping around the entire circumference. All of these sutures are en-

tirely within the vagina. Two or three superficial sutures of catgut through the skin complete the operation. When the rupture also involves the sphincter and rectal wall, the opening beyond the sphincter is stitched up with a continuous catgut suture, after which the operation is the same as already described. After this operation, Dr. Goffe claims, the patients are free from pain, and they require little or no after-treatment. The operation can be done very successfully in tenement-house practice, the patients getting up to the commode on the day following the operation.

Dr. George M. Edebohls, of New York, in discussing the foregoing papers, expressed his personal gratification at the evidence shown in Dr. Hayd's paper that the profession was gradually coming around to a full acceptance of the Alexander operation as a perfectly physiological procedure, and, indeed, the only legitimate one for movable retroversion of the uterus. He favored opening the entire inguinal canal and then doing a Bassini operation. This, in his opinion, would leave the canal as strong as, if not stronger than before.

Dr. W. Gill Wylie, of New York, thought the Alexander operation was an ideal one in a certain limited class of cases, but he had seldom performed it, because, when all the associated conditions had been cured by well-known means, there seemed to be little need for this operation. The operation was only a simple one, when done by an experienced surgeon. The paper of Dr. Cragin was a complete expression of his own views regarding vaginal operations. The next step in this field should be to endeavor to restore the normal shape and size of the vagina. The paper of Dr. Goffe contained certain views which he had himself embodied in two papers, prepared some time ago. He believed that the function of the perineum was an active one, and that when it was ruptured some of the tissues were inverted, while the external muscles became everted.

Dr. Vanderveer, of Albany, took much the same view of the Alexander operation as did Dr. Wylie. The operator who essayed to employ the vaginal route must be thoroughly familiar with the anatomy of the region. He had probably been the first to resort to the vaginal route, in an operation done about eighteen years ago.

Dr. Sears, of Syracuse, said that his own observations served to corroborate what had been said about the shoulders being largely responsible for lacerations of the perineum.

Dr. Ford, of Utica, said that the surgeons of his city were very much pleased with a method of suturing the perineum which was very similar to that described by Dr. Goffe. At first the sutures were not passed through the mucous membrane, but about one-fourth of an inch within the denuded surface. Then, the end of the suture on the left side being taken, it was crossed over and passed in deeply on the other side.

The Other Kidney in Contemplated Nephrectomy.—Dr. George M. Edebohls, of New York, read a paper with this title. He said that while the presence of another kidney, in a case of contemplated nephrectomy, could usually be determined by palpation, this method of examination did not suffice, for it left out of consideration altogether the condition of the kidney. The fact of the existence of another kidney could also be proved by examination with the fluoroscope, as had been demonstrated by Dr. Samuel Lloyd. The cystoscope furnished useful information, as did also catheterization of the ureters, more especially in the female; but these methods did not fulfil all the requirements, and, moreover, in cases of pyuria and in tuberculosis there was a real danger of infecting the healthy kidney by catheterizing the ureters. For these reasons he advocated a lumbar exploratory incision—a procedure which he believed to be original. By this method the kidney to be examined was not only exposed but was delivered through the lumbar incision, thus allowing a critical examination. When this mode of examination was carried out in strict accordance with his technique, Dr. Edebohls claimed, the danger of the procedure was but slightly greater than that of ureteral catheterization.

Dr. Bristowe was of the opinion, based upon a large experience in the dissecting-room, that an individual having only one kidney was so extremely rare that it hardly justified such a serious examination. He had met with three cases in which one or both kidneys had been situated abnormally low, and had had an anomalous blood supply.

Dr. Willy Meyer supported the position taken by Dr. Edebohls. He described the aid to be derived, in tuberculosis of the kidney, from cystoscopic examination, and cautioned against too hasty conclusions regarding the dangers attendant upon catheterization of the ureters, in both the male and the female.

Dr. Edebohls said that he had personal knowledge of three fatal cases of nephrectomy, in each of which it was ascertained afterward that the only kidney the patient possessed had been removed. An accurate knowledge, at the time of operating, as to the condition of the other kidney would enable the operator to decide the very important question of whether nephrotomy or nephrectomy should be performed.

The Past, Present, and Prospective Methods of Treatment of Insanity in the State of New York.—Dr. P. M. Wise, of Albany, after briefly reviewing the treatment of insanity in the past, criticised the lack of proper instruction on this subject in our medical schools and the slight interest taken by physicians in general in the work of the State hospitals. He called the attention of physicians to the dangers of narcotism in the early treatment of the insane, and to the disaster that had too often been the price paid for household quiet. The present enlightened methods of treating the insane in our hospitals were founded upon the removal of toxins and all nervous irritants, the improvement of the general health, and the development of the body to a normal condition of resistance. The policy of the State government was based on the fact that every insane patient cured meant a saving to the State of the maintenance of one person for twelve years—the average duration of insane life.

Dr. Landon Carter Gray, of New York, while admitting that many improvements had been made in our insane hospitals in recent years, alluded to some of the inherent defects of the system. "Why is it," he queried, "that in spite of all the millions spent by the State of New York on its insane hospitals, not a single new discovery in the pathology or therapeutics of insanity has come from any one of them?" The medical staffs of these hospitals were in isolated places, and were not sufficiently in touch with prominent neurologists and alienists. Again, the immense mass of valuable clinical material in these hospitals should be made available to all medical schools desiring to give instruction on mental diseases.

Dr. Wise replied that the lunacy commission was doing its best to make this clinical material available.

Actinomycosis.—Dr. J. E. Walker, of Hornellsville, in a paper on this subject, gave a brief historical sketch of our knowledge, supplementing it with some personal experience. In regard to treatment, he said that of late years iodide of potassium in large doses had come to be looked upon as almost a specific in actinomycosis.

A Year's Work in Appendicitis.—Dr. Herman Mynter, of Buffalo, read this paper. He classified appendicitis under three heads, viz., (1) simple catarrhal, (2) ulcerative, and (3) infectious appendicitis.

These, it must be understood, often overlap more or less. Under medical treatment of all cases, he said, the mortality is surely between sixteen and twenty per cent.; but of the eighty per cent. of recoveries, about fifty per cent. relapse, fifteen or twenty per cent. terminate fatally in the second attack, and a similar number in the third attack. Under early surgical treatment of all cases, the mortality should not be over four per cent. The chronic cases have no important mortality under laparotomy. In his own surgical practice, in seven recent cases of perforation and local abscess there were six recoveries; in ten cases of total gangrene without perforation there were eight recoveries; in nineteen cases with gangrene perforation there were nine recoveries.

Lessons from Six Cases of Appendicitis.—Dr. W. B. Jones, of Rochester, in a paper with this title, described six cases, selected as types. A good rule, he said, was to operate whenever an opiate seemed to be required.

Dr. Willy Meyer objected to considering every case of appendicitis a fit one for immediate operation, but he advised that all cases should be under the joint observation of a physician and a surgeon, and the latter should, if possible, postpone operation until after the first attack. Then would be the time of election for that beautiful blunt-division operation of McBurney—the ideal operation for appendicitis.

Congenital Dislocation of the Shoulder Backward, with a Report of Seven Cases, and an Operation for its Relief.—Dr. A. M. Phelps, of New York, presented this contribution. He said that the first case of the kind that he had seen was in 1895, and he could then find only six other cases on record. Since that time he had seen seven cases, showing that these cases in the past had seldom been recognized. Apparently they had been looked upon as cases of "obstetrical paralysis," yet in every one of the four cases in which he had operated there had been an old fracture of the glenoid cavity. In a case of this kind the elbow stood out from the body, turning forward and outward, the palm of the hand turned backward, and there was a certain degree of fixation of the shoulder. The operation which he had done consisted in making an incision along the posterior border of the deltoid, incising the capsule of the joint, cutting away the new articulation underneath the spine of the scapula and the head of the bone, and, after rounding off the bone, reducing the dislocation. The capsule was sutured behind the head of the bone, drainage inserted, and the wound closed. The results had been very good.

Dr. Louis A. Weigel, of Rochester, believed that some of the cases of "birth palsy" were due to injury to the central nervous system at birth, but he coincided in the main with the etiology as given by Dr. Phelps. In some instances he believed the shortening of the arm was not the result of the dislocation proper, but of the trophic disturbance.

The Treatment of Rachitic Deformities.—Dr. Reginald H. Savre, of New York, read this paper. He spoke of the value of the internal use of cod-liver oil and phosphates, and of the importance in the early stages of correction of the deformity by means of apparatus or by manipulation of the flexible bones. Later on osteoclasis or osteotomy would be demanded, and here it was important to attend carefully to the subsequent protection of the bones, in order to insure a good ultimate result.

Dr. Ransom said that as he had found among the Indians so little rachitic deformity, although an abundance of rachitis, he had been led to attach much importance to their bandaging of the infant—the papoose—as a prophylactic against such deformity. Some years ago he had suggested the use of a basket contrivance, on the principle of the wire cuirass, and would again urge its claims to recognition.

Dr. A. M. Phelps expressed his preference for osteoclasis over osteotomy, and, with Dr. Sayre, indorsed the "basket treatment."

Discussion: The Management of Hypertrophy of the Prostate Gland, and its Complications.—Dr. L. Bolton Bangs, of New York, opened this discussion. He expressed the belief that hypertrophy of the prostate is present in many men long before it is suspected, and attributed this to (1) early masturbation, (2) early association with lewd women, (3) adultery and fornication, (4) sexual excess and efforts at preventing conception after marriage. He then spoke of the establishment of catheter life and of the modern methods of maintaining sterile catheterism.

Prostatectomy and Prostatotomy.—Dr. S. Alexander, of New York, in discussing this subject, said that an analysis of two hundred and five operative cases showed that the mortality had been twenty-one per cent., and that sixty-two per cent. had been cured, *i.e.*, had regained the power of voluntary micturition. Well-marked arterial sclerosis or advanced kidney disease was a contraindication to these operations.

Bottini's Galvano-Caustic Treatment.—Dr. Willy Meyer exhibited the instrument used in this operation and described the technique. The operation is done under cocaine anæsthesia, several grooves being burned in the prostate.

Castration for Hypertrophied Prostate.—Dr. L. S. Pilcher, of Brooklyn, reported upon ten cases in which he had used this method. The ultimate results had been good, and there had been no mortality.

Stone in the Bladder and Hypertrophied Prostate.—Dr. E. L. Keyes, of New York, in treating of this subject, stated that he was becoming more and more convinced of the advisability, in cases of enlarged prostate with a very small stone in the bladder, of doing a suprapubic lithotomy and a partial prostatectomy, instead of, as he had formerly advocated, performing litholapaxy. The mere size of the prostate is not a factor in the problem. If lithotomy be performed, the suprapubic route should be selected, as it allows lowering the vesical end of the urethral floor.

Excision of the Fibula for Sarcoma.—Dr. Samuel Lloyd exhibited a woman of twenty-two years, upon whom he had done this operation in June, 1895. She is in good health and walks perfectly.

Treatment of Fracture of the Femur in Children.—Dr. Theodore Dunham, of New York, described a simple "interrupted" splint of plaster of Paris and flat iron braces, that he had found very serviceable in these cases.

Anniversary Address: "The Obligations of the Physician and the Layman to Each Other."—Dr. Seneca D. Powell, of New York, delivered his address in the evening, taking for his theme the mutual relations of physicians and laymen. He touched upon the abuses that had arisen under lay management of hospitals and dispensaries, and asserted that the intricacies of this problem were largely the result of the peculiar jealousy which existed between physicians. If physicians would respect the rights and privileges of one another, this problem could be readily solved without the intervention of the law.

Officers of the Society.—The nominating committee recommended that the following be the officers for the ensuing year: *President*, Dr. John O. Roe, of Rochester; *Vice-President*, Dr. E. F. Brush, of Mt. Vernon; *Secretary*, Dr. Frederic C. Curtis, of Albany; and *Treasurer*, Dr. C. H. Porter, of Albany.

State Board of Examiners.—The following were also reported favorably: Drs. Eugene Beach, of Gloversville; J. P. Creveling, of Auburn; H. D. Wey, of Elmira; and Daniel Lewis, of New York.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, January 18, 1898.

LOUIS FAUGÈRES BISHOP, M.D., CHAIRMAN.

The Significance of Albuminuria in Otherwise Apparently Healthy Persons.—DR. BRANDRETH SYMONDS read a paper with this title. He said that by the term "albuminuria" was meant a solution of serum albumin or serum globulin in the urine. The proportion of these substances varied in different cases, but when one was present the other was also. The kidneys were by far the most common source of the albumin, and it was to this form that his remarks would be confined. Many mild and curable cases showed much albumin, whereas in one form of chronic Bright's disease there was little or no albumin present; hence the quantity of albumin bore no direct relation to the prognosis.

Tests for Albumin in the Urine.—When the amount was not sufficient to give an immediate reaction with Heller's test, many errors in observation were likely to arise. The most common source of error was undoubtedly the nucleo-protein. According to his experience it was very frequently found in urine in small quantities. Up to a few years ago this substance had been confounded with mucin, because of its physical properties. It was readily precipitated by all organic acids, and also to some extent from acid urine by boiling. These facts cast grave doubts upon the accuracy of most of the tests for albumin. He did not know of a single test for albumin which was infallible. The more delicate the test, the less reliable was it. In his own practice, in testing the urine for albumin, if the urine was not sufficiently acid it was made distinctly acid by the addition of two or three drops of acetic acid, and then the upper layer in the test tube was boiled, and compared in a good light with the lower layer. If no reaction was obtained, he was satisfied that there was no albumin present of clinical importance. If an opacity was observed, he added a few drops of nitric acid. If the opacity remained, it was due to either nucleo-albumin or albumin, and to distinguish between them he used Heller's test. The sharply defined reaction obtained with albumin and Heller's test could not be confounded with anything except certain oleo-resins occasionally present in the urine. As ordinarily applied, this test was not very delicate, but if urine so treated was allowed to stand for several hours the presence of very small quantities of albumin would be indicated. Although sometimes he employed other tests he always checked them with Heller's test. From the fact that his records showed that he found albumin in the urine much less frequently than formerly, in spite of increased experience in testing for albumin, he had been led to believe that in his earlier years he had sometimes been guilty of confounding albumin with nucleo-protein.

Varieties of Albuminuria.—Cases of albuminuria could be broadly and conveniently classified into two groups—organic and functional. Among the transient albuminurias, those of acute nephritis were the most frequent, and they often completely disappeared. Most of those subjects of albuminuria applying for life insurance should be classified as functional. These might be subdivided into several varieties: (1) There was the psychical variety, in which the albumin was scanty or absent in the morning urine, increased toward noon or early afternoon, and then disappeared for the rest of the day. These persons were usually dyspeptic and anæmic. It was a curious fact that most cases of Bright's disease showed similar diurnal variations in the quantity of albumin in the urine. (2) There was a dietetic variety, supposed to be caused by highly nitrogenous articles of food, such as milk, eggs, etc. He had never seen a case which he felt sure was of this class. (3) There was the muscular variety—that form in which the albuminuria was caused by severe muscular exercise. It came on very soon after the exercise, and lasted usually for days or weeks. It was quite common in these days of bicycle riding and active outdoor sports, and was usually found in persons under thirty years, but might occur in those much older. (4) There was the albuminuria of adolescence, found in persons between the ages of fifteen and twenty-three years. It was quite common among boys, who were sometimes anæmic, but frequently in robust health. In some cases the urine would be concentrated and loaded with urates, but in many it seemed to be normal, except for the presence of albumin. The albuminuria sometimes persisted for a long time without causing any apparent trouble. Dr. Symonds recalled a case beginning in a boy of seventeen years. After two years it assumed the muscular type, lasted three years, and then disappeared entirely. The urine had been examined many times since then, but without finding any albumin. In this age of sexual excitement it was not surprising that nucleo-protein should be found in the prostatic portion of the urethra. (5) There was a variety of albuminuria said to be the result of irritation by highly concentrated urine. In this connection it should be remembered that the urine of birds and reptiles was so concentrated as to be almost solid. The persistent excretion of saccharine urine would also cause albuminuria. (6) Another variety of transient albuminuria was that associated with influenza and ordinary colds. It had been quite common in his experience, and usually disappeared within a few days after the acute febrile disturbance had subsided.

Clinical Significance of Transient Albuminuria.—We should regard all albuminuria, whether transient or permanent, as pathological. Albuminuria was no more physiological than a heart murmur, although like the latter it might disappear entirely and permanently. He knew of no way of distinguishing the mild cases with good prognosis from the more serious forms, except by the continued absence of albumin from the urine—in other words, as long as albuminuria persisted there was a possibility of the development of some serious organic mischief. The longer the albuminuria persisted, the greater the probability of its organic origin, and if it lasted for more than a year the prognosis was doubtful, although not hopeless. A continuous albuminuria was more serious than one which came and went. The presence of renal casts was usually considered as indicative of organic renal disease, but some claimed to have found these casts in other varieties, particularly the muscular form of albuminuria. Again, some observers claimed to be able to distinguish with certainty renal epithelial cells from those of the bladder, but personally he could only express his profound admiration for such remarkable skill. If the specific gravity of the urine continued below 1.015, it was a bad prognostic sign, generally indicating renal insufficiency. These cases were much less amenable to treatment than those having a specific gravity of 1.025 or higher. A hard pulse with an accentuated sound at the closure of the aortic valves was indicative of something more than functional disturbance. Frequent or severe headache in conjunction with albuminuria might also be regarded as of evil omen. The younger the age down to childhood, the more likely was the albuminuria to be functional: if the age was over forty, the cases should be regarded with a suspicion, which increased with every year. The most advanced age at which he had observed albuminuria in a man otherwise healthy was seventy-

two years. In this individual there was no evidence of organic disease. Another bad prognostic sign was an extremely low or an extremely high body weight. A very light weight was often associated with the albuminuria of the young, and in many instances seemed to be due to the albuminuria. On the other hand, overweight with albuminuria was apt to occur in persons over thirty years of age, and was of graver significance than underweight. A particularly unfavorable combination was albuminuria with the constant moderate use of alcoholics. In still another class albuminuria persisted steadily, although the individual was apparently in good health otherwise. These cases were certainly very puzzling. The amount of albumin was usually very small—a "trace"—and in most of them undoubtedly nucleo-protein had been mistaken for albumin. The hypothesis had been advanced regarding these cases that an acute nephritis had occurred and passed away, leaving a small but non-progressive lesion in the kidney. The remainder of this organ being sufficient to carry on the work, the general health was not impaired. The theory was plausible, but was unsupported by post-mortem examination. From an insurance standpoint he would not admit that such persons, as a rule, lived as long as others.

Life-Insurance Examiners Look through an Albuminous Haze.—Dr. S. S. Jones said that the positions occupied by the general practitioner and by the life-insurance examiner sometimes seemed to be antagonistic. When albumin was found by acetic acid and boiling, or by Heller's test, it was right for the family physician to state to his patient that his rejection by the life-insurance company was well-founded; but it had happened repeatedly with him and others that no albumin had been found. The reason for this was that life-insurance examiners had employed too delicate tests. For example, one of his patients had been rejected by a life-insurance company fifteen years ago. This individual had been under his observation ever since then, and an examination of the urine two days ago showed a specific gravity of 1.022 and 1.024 for the morning and evening specimens respectively, an absence of sugar and casts, no albumin by Heller's test or by acetic acid and boiling, and only an equivocal reaction with the ferrocyanide test. During these fifteen years the man had been in excellent health. In another case a man had been rejected by two large companies in this city and accepted by a third. He had obtained no reaction in this urine with Heller's test or the ferrocyanide test, or on boiling; there was a sufficient quantity of urea excreted in the twenty-four hours, and he could find no reason for the rejection.

Spurious Albuminuria.—Another source of error was "spurious" albuminuria. He thought some of the albuminuria of adolescence was due to spermatorrhœa and congestion of the genital canal, possibly from masturbation. One of his patients he was sure had been declined some years ago because of a slight cloud in the urine, due to a trace of an old urethritis. He stated this, because no reaction had been obtained with the urine after the canal had been carefully washed out. Life-insurance examiners unfortunately too often took a one-sided view of a risk. He could recall every year a number of patients who had been accepted, who certainly were not good risks, chiefly on account of intemperance. He protested against looking at the applicant for life insurance too much through this little albuminous haze. In his opinion it did not follow that patients with slight albuminuria did not pass well through the acute diseases, provided their habits were good.

Consider the Individual.—Dr. F. W. Jackson said that apparently the life-insurance examiners were not any more certain regarding the significance of albuminuria than was the general practitioner. The larger his own experience, the less satisfaction he derived from speaking about "albuminuria." He had known a very considerable quantity of albumin to persist in the urine for a long time without any apparent deterioration of the general health. He thought that in the class of patients seen at Bellevue Hospital fully eighty per cent. had chronic nephritis, and yet they showed considerable resistance to disease. In discussing albuminuria we must consider the individual with it, and establish our prognosis rather by the general health and habits than by the quantity of albumin in the urine. A gentleman had been under his care for ten or twelve years who had had a marked tuberculosis of one lung, from which he had entirely recovered, so that he was in active legal practice. At one time he had been surprised to find at least one-fifth of albumin by volume in the urine, as the history did not explain the condition. He had followed this man for ten years, and during all this time the albumin had existed in considerable quantity in the urine, with no deterioration of the general health.

Dr. W. Moore said that from the insurance records of over eight thousand cases he had found that albuminuria had been noted in about six per cent. The instructions to medical examiners issued by eight of the largest companies all stated that a trace of albumin was sufficient cause for refusing a risk, and several stated that even if that trace had disappeared and was again found it was good ground for permanently rejecting the applicant for insurance. In his experience stricture had been a common cause of slight albuminuria and of the rejection of the applicants. In these cases the specific gravity of the urine was normal, and the quantity of urea excreted was also within the limits of health. In every instance, after the stricture had been cured the individual had been accepted for life insurance. Albuminuria, he believed, was due either to disease of the walls of the renal blood-vessels or to increased blood pressure. When dyspepsia and disease of the liver, heart, and blood-vessels could be excluded, he thought the albumin was probably the result of inflammatory changes along some part of the genito-urinary canal. It was common to find the quantity of urea normal in cases of intermittent albuminuria. He believed that as long as the percentage of urea was nearly normal the prognosis was quite good. The presence of albumin was often overlooked, owing to an improper application of the test. It was important to test the urine carefully with litmus paper before applying the heat and nitric-acid test, and also to allow the urine to stand for a half hour or more before positively deciding as to the presence or absence of albumin. It was quite conceivable that as a result of a simple congestion of the kidneys there might be a transient albuminuria, and that this might absolutely and permanently disappear. Nor did he see any reason why this should not occur in men over forty years of age. His experience had been that albuminuria was very common in those over weight.

Dr. W. Evelyn Porter said that the class of cases considered acceptable insurance risks at the present time was that in which there was not a true albuminuria, but rather a condition in which nucleo-albumin or mucin was found in the urine. Microscopical examination had often shown existing nephritis, and he thought the present tendency of the companies to avoid such examinations was a mistake. The presence of true serum albumin in the urine, even in small quantities, he believed should be considered a cause for at least temporary exclusion from life insurance. The majority of companies still held that as long as albumin existed in the urine the applicant should not be accepted, although some companies still accepted such ap-

plicants as "bad risks." This latter practice had been carried on longer in England than in this country, and with fairly satisfactory results. In considering the different standpoints of the general practitioner and the life-insurance examiner, it should be borne in mind that life-insurance companies must make certain rules, to which they can make but few exceptions, and that they did not have the same opportunity for considering in a broad way the general health of the applicants, as did general practitioners. If persons applying for life insurance, and found to have slight albuminuria, were referred to a careful clinical observer for prolonged observation, it would be possible to obtain after a period of years some very valuable information as to the clinical significance of albuminuria.

Serum Albumin Derived from Decomposition of the Blood.—Dr. Heinrich Stern said that if serum albumin was the only substance essential to true albuminuria, then we should ask if serum albumin could exist in the system. It was a proteid body which could not exist in life, as it was produced by the coagulation of the fibrin of the blood. If the serum as such could only be produced after the coagulation of the fibrin—in other words, after the decomposition of the blood, especially of the blood plasma—he did not see how we could say that serum albumin, which formed three or four per cent. of the serum, could exist in any physiological state; if it did, we should have thrombosis and embolism at the same time. Eisenbach had lately examined the urine of one hundred and thirty individuals who had been subjected to an anæsthetic. To sixty of them ether had been administered, and to the remainder chloroform. Albuminuria was found in twenty-five per cent. of the persons who had been etherized, and in forty-two per cent. of those with whom chloroform anæsthesia had been used—in other words, interference with the physiological activity of the system by the induction of general anæsthesia by ether and chloroform tended to produce a temporary disintegration of the blood. He was of the opinion that if the albumin in cases of albuminuria was serum albumin, it could be derived only from the blood. It was very probable that as a result of the non-elimination of certain substances the blood plasma was decomposed with the consequent elimination of the serum albumin.

Albuminuria Not Necessarily a Precursor of Renal Disease.—Dr. William Henry Porter said that he had for a long time been of the opinion that there was no such thing as a "physiological" albuminuria. He thought much of the confusion regarding albuminuria had arisen from the tendency to think that we were dealing with serum albumin. On the contrary he was inclined to believe that albumin found in the urine was an isomeric condition of the albumin as it existed in the blood, and that sometimes it might be one thing and sometimes another. We started always with the albumin as an alkali albumin, and it must be transformed into a peptone before it could get through the epithelial walls of the blood-vessels and into the blood. After having reached the blood it existed in three forms—serum albumin, serum globulin, and fibrinogen. The albumin in its transit through the body was constantly undergoing isomeric transmutations. Having gone through the body it came around a second time to the cells of the various glandular organs, and if the intake of albumin was not too great, and there was sufficient oxygen to enter the cells with the albumin, the proteid body would be oxidized in the cells of the liver and kidney, and would be eliminated as were the ordinary catabolic products—the excreta of the body. But if the individual took more albumin than he could oxidize (*e.g.*, in muscular albuminuria), the albumin could not be perfectly oxidized into urea, uric acid, creatin, creatinin, etc., and the protoplasmic tissue of the renal cells simply excreted that albumin as a catabolic excretory product. Looking at the subject from this standpoint, the albumin was not necessarily a forerunner of renal disease. Hence in people who eat more than they could readily oxidize, there might be for years a hypertrophic condition of the renal cells, allowing the excretion of the albumin, but not necessarily meaning that these individuals were going to have renal disease. He thought the more we studied these so-called temporary albuminurias the more we found that they were always associated with a clinical history of that kind. If this went on indefinitely, however, it must necessarily result in a degeneration of the kidneys. But it was a condition, he believed, which could be easily arrested, provided we could control the habits of life of the individual. In many nervous people the albumin was not properly oxidized, and hence was eliminated in the urine. In many of these instances, if the hypertrophic condition of the epithelial cells had not become too fixed, the condition could be completely cured, so far as the albuminuria was concerned.

Significance of Casts.—With regard to the casts, he would differ a little from the statement made in the paper, in that he believed that the cast was absolutely indicative of an abnormality. But the kind of cast was of much importance. He was of the opinion that in the majority of individuals, particularly in those who eat too much, and in whom there was a tendency to oxidation and overproduction of uric acid, hyaline casts could be found in the urine; the albumin was precipitated in the tubules, and the albuminous plug was washed out. The presence of hyaline casts, therefore, in the urine simply meant that an isomeric albumin had been excreted through the renal cells and had been precipitated by the uric acid. If with these casts there were epithelial cells undergoing various degrees of degeneration, there was reason to believe that the cells were desquamating with undue rapidity, and that there was evidence of positive renal disease. Of course for clinicians it was common to meet with a great variety of these casts, and yet there would be a rapid restoration of the individual to a perfectly normal condition. This was observed very frequently after the administration of ether. Probably if the cases were carefully examined, fully fifty per cent., and possibly even a higher percentage, of those subjected to prolonged etherization would be found to have in the urine after the third or fourth day an abundance of hyaline, epithelial, and nucleated casts. A very large percentage of these subjects recovered, and after a week or ten days no casts or albumin would be found in the urine. He recalled a very interesting case, examined by him before operation, in which there was absolutely no albumin, but the urine had a high specific gravity, and contained a large amount of urates and uric acid, and a few hyaline casts. The uterus and appendages were removed, the operation lasting about four hours. About twelve hours afterward the patient died, and within four hours he had had a section of the kidneys under the microscope. At the autopsy about half an ounce of urine was found in the bladder, and it contained a fair percentage of albumin and an abundance of casts. The tubules of the kidneys were loaded with hyaline, granular, and nucleated casts.

The Prognosis of Albuminuria.—He thought the clinician could state pretty accurately just what kind of an albuminuria was under observation. Regarding the prognosis, he said that the previous habits and methods of eating would determine the prognosis quite accurately in cases of albuminuria. If the patients were largely animal feeders, they stood the treatment remarkably well and a fair percentage recovered; but if they were largely vegetarian, or ate freely of fruits, a bad prognosis was usually warranted.

Albuminurics Not Good Insurance Risks.—Dr. Thomas W. Bickerton expressed the belief that the presence of albumin in the urine should always be looked upon as pathological, although the kidneys were not necessarily damaged. If the albuminuria persisted or recurred frequently, the kidneys were surely damaged. In his work as a life-insurance examiner, he had found that most of the simple cases terminated fatally. Out of one hundred and forty-eight cases he had been able to trace one hundred and fourteen, in a period of about eight years. Of this number thirty applicants had died. He thought, therefore, that life-insurance companies could not accept such cases under the ordinary rules of selection, although possibly a certain percentage might be accepted after careful study.

Albuminuria of Adolescence.—Dr. Paul E. Tiemann spoke of the albuminuria of adolesence, and cited a case that had been under his observation. He had first seen in 1892 a boy of fifteen years, who exhibited all the characteristic signs of psychical albuminuria. There was no albumin in the urine in the early morning, but it soon appeared and increased toward noon, and was scanty or absent at night. The urine also contained a good deal of uric acid, urates, and oxalates, and occasionally a few red or white blood cells in the sediment. In a number of microscopical examinations he had found only a very few casts, although the specimens had been examined by the ordinary method of sedimentation and by the use of the centrifuge. Dr. J. E. Weeks had examined the fundus of the eye twice in 1896, and again last March, and had found it absolutely normal. The boy had continued to grow and thrive, although somewhat under the standard of robust health. Six months ago he had been in good health. A few days ago the boy reported that he was not working, and, being in the house a good deal, was suffering from dyspepsia; yet the urine showed no trace of albumin and the microscopical examination was entirely negative. The speaker had never found evidence of spermatorrhœa. He would like to hear an expression of opinion regarding the ultimate fate of this individual.

Dr. Henry Dwight Chapin cited a case of a very nervous gentleman, aged forty-five years, who had applied for life insurance, and had been rejected. This had produced a very bad mental effect. Having restored him to good condition he had consented to the man's again applying for life insurance, believing that his acceptance would have a beneficial effect upon his mind. Just before the man went for examination Dr. Chapin examined his urine and found it free from albumin. The man then took lunch and went to the examiner, reaching the office in a state of excitement. He was again declined because of albuminuria. This time the albuminuria persisted for a considerable period. Dr. Chapin expressed the belief that the burden of proof often rested with the insurance companies, and that too many cases were rejected on insufficient evidence.

Dr. Symonds, in closing the discussion, said that in many cases of transient albuminuria the albumin disappeared within twenty-four hours. It was just such a case that had been cited by Dr. Jones this evening. He had known this to happen repeatedly, even when there was a considerable quantity of albumin present. The insurance company which he represented would accept such a case when assured of the continued absence of albumin. The rule with his company was to test for albumin; if present, to test again in two or three days, and after a week or two to test a third specimen. If three specimens contained albumin, the company postponed consideration for a period of a few months. In 1878, albumin had been found in the urine of a man in this city who obtained some little notoriety in the last political campaign. That albumin was almost constantly present, and had existed since the age of twenty-eight years. His expectation of life was thirty-seven years, making his estimated period of life sixty-five years. He died recently at the age of forty-eight—seventeen years short of the expectation. Dr. Symonds said that the companies were willing to make the investigations desired by the general practitioners if the applicants were willing to co-operate. They were not so much alarmed by the mere presence of albumin in the urine as formerly, but just as long as the albumin was present they had the right to be afraid to accept the risk. Functional disturbances of any kind, of the kidney included, were much less liable to occur after the age of forty years. In an investigation made some years ago, all of those in whom albumin had been found after the age of forty years, without exception, did not live out their expectation.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

NEW-YEAR HONORS — TYPHOID — ORRHO-THERAPY — NUMBERS OF THE PROFESSION INCREASING—DEATHS OF THE LAST YEAR—MEDICAL BOOKS OF '97—DENTISTS—INFLUENZA—MEMORIAL OF HAUGHTON—ZOÖLOGICAL SOCIETY—DEATH OF DRS. WARD, CLARK, WILLIS, CALDERWOOD, PATERSON.—THE DEBATE ON THE PREVENTION OF TYPHOID BY THE MEDICO-CHIRURGICAL SOCIETY—ADHERENT PERICARDIUM—SPECIAL DISCUSSION BY THE MEDICAL SOCIETY OF LONDON.

London, January 14, 1898.

The new year brought as usual a list of honors conferred by the Queen. It is a pretty full list, considering the number of distinctions conferred at the jubilee. The medical profession receives some knighthoods and orders, and this time Scotland obtains the share expected at the jubilee. Professor Gairdner becomes a K.C.B. A few years ago he declined the offer of a simple knighthood, to the gratification of his numerous pupils and admirers, who felt that distinction inadequate for the leading Scotch physician and clinical teacher, who is also physician to the Queen and member of the General Medical Council. The K.C.B. is a higher distinction, as the Order of the Bath takes such high rank among these distinctions. Professor Struthers, the great anatomical teacher of Scotland, and Dr. Batty Tuke, president of the Edinburgh College of Physicians, receive knighthood. Brigade-Surgeon Lieutenant-Colonel King gets K.C.B. He was superintendent of the Botanic Gardens at Calcutta, and succeeded in cultivating the cinchona tree in India, a service which has been of immense value to the empire. Surgeon Lieutenant-Colonel Thomson and Surgeon-Major MacCartie take C. B.

Though outside the profession, one well known to us, and to many of your countrymen who visit Europe, was the late principal librarian of the British Museum, Mr. E. A. Bond. From 1832 to 1888 he faithfully served his country—the first five years in the record office, the remainder in the museum. After these fifty-six years of work he retired. On Saturday came the announcement of his promotion to the K.C.B. The next day he died, at the age of eighty-two. Had the distinction been given when he retired, nearly ten years ago, it might have been acceptable. But to offer it to a dying man!

Typhoid is still the leading topic with us. Maid-

stone is rejoicing over the conclusion of her trial, and on Sunday last thanksgivng services were held in all her places of worship. At Lynn only seven new cases were notified for the week, and the deaths remain at forty-three. The water supply, however, is causing no little anxiety, and it is hoped the new works will be carried out as rapidly as possible. At Camborne, since December 5th, when the first case was notified, the number has gone on increasing and is now above eighty. A doubtful water supply was cut off a fortnight ago, and the whole is now obtained from one source, said to be above suspicion.

The adjourned discussion on the prevention of this disease will be resumed by the Medico-Chirurgical Society next week. Meanwhile the Pathological Society has been considering another aspect. At its meeting on Tuesday Dr. T. J. Bokenham took up the orrho-therapy of typhoid, and pointed out that the principles involved differed essentially from those applicable to diphtheria and tetanus. There is, he admitted, no definite proof that true toxins are produced by Eberth's bacillus or by the streptococcus. It is not, therefore, justifiable to speak of a typhoid or streptococcus antitoxin. Yet clinical observation seems to show that serum from animals immunized against typhoid cultures has valuable therapeutical effect. Having pointed out the distinctions between Eberth's bacillus and the bacillus coli, and given some account of his experiments, Dr. Bokenham concluded that non-toxic filtrates of fresh cultures have distinct immunizing power; that the immunizing action is displayed toward both living and dead cultures; that the serum of animals treated with filtrates of fresh cultures acquires agglutinative and bactericidal properties; that mixed in sufficient proportion with living cultures the serum renders them harmless; and that to some extent the serum has preventive and curative powers. On the toxic filtrates of old and dead cultures Dr. Bokenham admitted with other observers that the serum had no antitoxic properties, but he did not despair of obtaining a serum which would possess such powers.

There is no doubt now that we shall follow the example of the continent, and store glycerinated calf lymph for vaccination. The report of Sir R. Thorne and Dr. Copeman on their tour of investigation is altogether in favor of the plan. The best laboratory in connection with the vaccination institutions which they visited was at Cologne, but in all the utmost care and cleanliness prevailed. They recommend that calf lymph be exclusively used, and that the distribution from the national establishment should be limited to glycerinated lymph. To carry out the plan the existing animal vaccine station will have to be reorganized. A properly equipped laboratory should also be added under the supervision of an experienced bacteriologist.

The 1898 Medical Directory has been delivered this week. It grows thicker every year. The number of practitioners included is 34,903—an increase of 619. This number includes the naval and military officers and practitioners settled abroad. The London list extends to 6,081; the provincial in England to 15,400. Wales has 1,081; Scotland, 3,412; and Ireland, 2,615. In spite of the overcrowded state of the profession the increase seems to continue, and what the young men now qualifying at the colleges will do to secure a living no one seems to be able to guess. The deaths recorded for the year number 599, or an average of about 1.75 per cent.

The medical books published last year were two hundred and eleven, of which one hundred and fifty-two were new works and fifty-nine new editions. This is more than one hundred above the number for 1896, but about the same as in 1895. These numbers are given in the *Publishers' Circular*, but it may perhaps be permissible to feel a doubt as to the classification adopted, for books called medical by the public are some of them such as the profession would scarcely acknowledge as its products.

The dentists are crying out for representation on the Medical Council, as they contribute a considerable amount to its income. Several incidents have occurred which show that a dentist's advice would be advantageous. They should press the government to select a dentist for the next crown vacancy.

Influenza has been rather prevalent during the last month, but scarcely amounted to an epidemic. The deaths registered in the last four weeks from the disease have been ten, seventeen, fifteen, and twenty-nine.

It has been decided in Dublin to erect a memorial to the late Dr. Haughton. This is promoted by the Dublin Zoölogical Society, of which he was president, and will probably take the shape of a building in its gardens. I wonder if it was due to his influence that the Dublin Zoo has so long been better managed than ours. The London Society should look to this. It is to be feared that scientific zoölogists do not make their voices heard in the London society, and leave the management of the gardens to traditional notions. With the International Congress of Zoölogy approaching, the London society should awake to its responsibilities.

Dr. Montgomery Ward, surgeon to Mercer's Hospital, Dublin, died unexpectedly at the close of the year. He had been a little out of health lately, but was not thought to be suffering from serious disease; in fact, he was at his work on Tuesday and dead on Friday. His death removes the last of the old staff at Mercer's; so now only those remain who applied for the vacancies so irregularly made, and who, I suppose, will be ready to be as summarily removed as their predecessors when the board thinks it pleasant to show off its importance.

The late Mr. O'Grady, you will remember, was about to fight this in the law courts, but death intervened. A memorial is being raised to him, and nearly £200 has already been collected.

The death of the Rev. T. E. Clark, M.D., took place on Christmas eve. He was once surgeon to the Bristol Infirmary. Some years ago he left the medical profession for the church, but he retained the respect of both until his death, in his sixty-third year.

Dr. J. A. Wallis, one of the commissioners in lunacy, died suddenly, on the 30th ult., from angina pectoris, of which he had previously had attacks. He had had great experience in asylum work before being appointed to the commissionership, in which office he gave great satisfaction.

The death of Dr. Calderwood is also announced. He was a young man of great promise, who graduated at Glasgow University in 1896 after a brilliant career as a student, and was then appointed demonstrator of anatomy.

Another promising young man's career is closed in early death—Mr. W. H. J. Paterson, house surgeon at St. Thomas' Hospital. He died on the 2d inst., after a few days' illness. He was, in fact, at work on December 26th, next evening felt rather ill, and soon jaundice appeared, followed by delirium and then coma.

LONDON, January 14, 1898.

THE adjourned discussion on the prevention of typhoid fever has now occupied two evenings, and the space at my disposal precludes more than a brief notice of the most important points. Special interest attaches to the debate, as fresh outbreaks of the disease have occurred.

Dr. Payne thought it not impossible that the bacil-

lus might exist as a saprophyte, and became pathogenic only under certain conditions. Moreover, he thought it likely that the fever could be taken in certain cases by inhalation. Cotton and linen garments were easily disinfected, but woollen ones were scarcely ever made safe by the usual washing.

Surgeon-Major Jameson (director-general of the army medical department) discussed the relative frequency of the disease in various countries. From his statistics it appears that in India it occurs in young soldiers and recent arrivals, women and children suffering less frequently than men; it appears also in isolated cases distributed over wide areas and in posts occupied for the first time.

Professor Kanthack said it has been shown that the bacillus exists in the pus of abscesses formed during an attack, and may be found in abscesses years after the attack. So, too, it has been found in the gall bladder years afterward. It is not known how long it may remain in the fæces, but the cholera bacillus persists long after the motions have become solid, so it is probably unsafe to consider a patient free from infection as soon as he has recovered from the attack. The bacillus has been found in ploughed land when typhoid almost certainly could be excluded; it could multiply in the soil and find access to water supplies. Dr. Kanthack suggested that disinfection of intestines taken from typhoid cases should be more carefully attended to in post-mortem rooms.

Dr. Sims Woodhead said that cisterns might be a source of infection to the family, but were protective to the mains, in which it is impossible to keep the pressure constant. It was, he thought, easy to check an epidemic from milk compared with one due to water infection, and he considered frequent, almost constant, examination of the water desirable. The cholera bacillus may be present before an attack of the disease, and it may very likely be found that the same is the case in typhoid. The bacillus coli and that of typhoid grow under very similar conditions, so that where one flourishes the other is likely to flourish also.

The debate was renewed on Friday, when Dr. Corfield took the part of the water system, which had been assailed by Dr. Poore. The latter, however, had not proposed to do away with water carriage in large cities, and in his reply complained that some speakers had scarcely represented his remarks accurately. Dr. Corfield said that London shows a lower death rate from typhoid than all England and Wales; but it is the city in which it is the most universal. Till lately it was thought this fever might arise *de novo* from decomposing excrement, but he had shown twelve years ago that isolated cases occurred only when a fresh case was introduced from without. Until lately one of the chief sources of propagation was the connection of cistern waste pipes with soil pipes.

Dr. Seaton referred to the reduction in the mortality of typhoid, amounting to no less than sixty per cent., and urged the extension of notification and the efficient organization of the sanitary service as the chief points in prevention. He accepted Dr. Poore's views for rural districts, but not for large towns. He even admitted that there are many such districts, where elaborate systems of water carriage have been carried out, where the dry method would have been safer as well as better.

Dr. Squire said that in hot, dry climates the disease was spread through dust carried by the wind.

Dr. F. Little proposed universal notification, compensation to bread winners, municipal laboratories, supervision, inspection, and exclusion of excreta from the soil.

Dr. T. Williams attributed something more than had been admitted to the vulnerability of the individual and of the Anglo-Saxon race.

Dr. Horton Smith referred to the long time the bacilli persisted in the excreta—twelve days after defervescence according to one observer, and forty-one according to another. He had himself detected them twenty-two days after, and therefore disinfection should be carried out in the most complete manner during convalescence. Even after the bacilli have disappeared from fæces and urine, they may remain in the marrow of the bones and set up osteomyelitis. In two cases they have been found in a cavity containing a sequestrum six years after the attack. He would advise burning the excreta where possible, and thought it dangerous to put them on the soil, as the bacilli had been shown to grow there.

Mr. H. E. Durham said that much that has been written on the bacillus is not to be relied upon, as the tests employed have been imperfect and there are several organisms which grow under similar conditions. He did not consider Widal's test, as it is usually applied, of much clinical value.

Dr. Childs would hold water companies responsible and give sanitary authorities more power, and said Munich might be instanced as showing what sanitation could do, for it had reduced the typhoid mortality of that city to one-twentieth of its former rate.

Dr. Seymour Taylor commented on some clinical points, and, in reference to the proclivity of newcomers to suffer, suggested that perhaps the dwellers in a house might have become immune from long exposure to the poison.

Dr. Poore, in reply, defended his position, but of course had not time to answer each speaker in detail or to refer to all the points raised. As to India, he referred to the natives washing in tanks and the thirst of the tropics inducing men to drink water of any kind. Then, he said, though the mortality is high in India, it is low in China, where the fæces are applied to the soil. With reference to the bacilli growing in the soil, it should not be forgotten that they flourish most in filthy soil. Excreta should not be thrown into a deep trench, but laid on clean soil and covered with a small quantity of fresh earth—a plan as old as Moses, as recorded in the Pentateuch.

On Monday evening the Medical Society held the discussion of which notice had been given, on "Adherent Pericardium." Sir William Broadbent opened by reference to the difficulty of diagnosing the condition, which may easily be overlooked, as it does not always set up any marked disturbance of the heart's function. An approximate diagnosis can be made by considering the probable effects of other lesions present and the significance of symptoms which those lesions cannot themselves produce. Dilatation and hypertrophy without valvular affection suggest the possibility of adherent pericardium, and sometimes a distinct systolic tug is given through the diaphragm to the left false ribs. Though the condition may not be giving rise to symptoms, it is not without importance, as it may aggravate bronchitis, interfere with compensatory hypertrophy, and in old age favor degenerative processes.

Sir Douglas Powell followed. He remarked on the untrustworthiness of the signs which have been considered pathognomonic. He said that often when the condition is diagnosed during life the post-mortem shows no such condition; on the other hand, the autopsy often reveals a very marked adhesion which had never been suspected during life.

Dr. John Broadbent quoted the late Dr. Sturges, to show that only six out of one hundred cases of heart disease in children escape adhesions. He directed attention to the early appearance of increased dulness due to dilatation. Adhesion formed during this state will interfere with the return of the heart to normal size, and the speaker therefore inferred so that when

the organ remains permanently enlarged the adhesion has taken place early.

Dr. Ewart did not accept the common notion that the right side of the heart is most affected by adhesion. On the contrary, it seemed to him that when adhesion causes limitation of the movement it is the left ventricle that must be incommoded.

In his reply Sir W. Broadbent said he could not accept this view, as the symptoms of cardiac failure associated with adherent pericardium certainly point to the right heart.

Dr. S. West and Dr. Lees had in the mean time spoken, the former insisting that dilatation is the rule—not hypertrophy; the latter calling attention to the rapidity with which dilatation occurs in acute rheumatism. This he thought due to the toxic influence of a microbe.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE NEW YEAR—PROFESSOR JACCOUD—PRESIDENT OF THE ACADEMY OF MEDICINE—RADIOGRAPHY OF THE CRANIUM AND LUNGS—A MEANS OF ERADICATING TUBERCULOSIS FROM THE ARMY—ELONGATION OF THE SPINAL CORD—MASSAGE IN THE TREATMENT OF FRACTURES, ETC.

PARIS, January 7, 1898.

THE advent of the new year in Paris is not an occasion of any special note professionally. There is, of course, the vacation at the academies and the Ecole de Médecine; also there are a few doctors' receptions and dinners, but ill people must be attended to, whether in the hospitals or in private practice, so that the medical profession moves on while the rest of the world stops for a moment to enjoy the festivities of New Year's, the greatest day of the year in France.

The year is so very young yet that we must look to 1897 to find anything of unusual interest. The dying year was marked at the Academy of Medicine by Professor Jaccoud taking the chair of president and Professor Panas that of vice-president, occupied last year by Professor Jaccoud. Those two elections are universally applauded. Professor Panas, a Greek by birth, and professor of diseases of the eye at the Faculty, has written voluminously, and is one of the leading authorities on diseases of the eye to-day. His works on inflammation of the membranes of the eye, on retinitis, on diseases of the lacrymal system, on the nasal fossæ and the lacrymal ducts, strabismus and ocular paralyses, were worth to him a nomination to the chair of ophthalmology in 1879 and an election as member of the Academy of Medicine.

At this meeting of the academy, Professor Le Dentu presented an apparatus exceedingly ingenious and one likely to prove of the greatest value in surgery. It was conceived by M. Contremoulin for cranial radiography. Professor Péan in his turn presented another apparatus of the same sort. Although Professor Péan's instrument, if it may be so termed, appeared to be less perfect or perfected than that presented by Professor Le Dentu, it had the advantage of being more maniable. It was invented by M. Mergyer. By means of either or both of these instruments, looking for intracranial projectiles, such as bullets, bits of glass, bone splinters, ends of steel instruments, or weapons, etc., becomes greatly facilitated and simplified, and we all know how difficult, groping, and even perilous it has been up to the present time. But the most important and far-reaching application of the Roentgen rays is that proposed by Professor Kelsch, one of France's most eminent military doctors, and is nothing less than the precise precocious diagnosis of pulmonary tuberculosis. Professor Kelsch brings us the possibility of promptly eliminating from the army all those young latent tuberculous patients whose disease cannot be detected by the ordinary means of percussion and auscultation, but who soon become worse, contaminate their comrades, and finally, too late, are reformed, as the French say—that is, taken out of actual service. The great value of this application of the Roentgen rays is apparent when we consider the alarming number of such cases—one or two cases in five soldiers examined. The number of men in the service will be thus diminished very sensibly. That, I admit, is a drawback from a military standpoint, but only apparently. On the other hand, how many young men saved from the overcrowding in barracks, dampness, hard tasks, and exposure to the weather, may be returned to the pure air and simple life of the country, at a period when tuberculosis is still curable! I have known such cases cured simply by living in the country and riding on horseback. And when we think that one-fifth of the total mortality rate is due to tuberculosis, we are more than ever impressed with the great scope of usefulness of the Roentgen rays in this particular, to say nothing of its application to civilians.

Dr. Kraus next occupied the attention of the academy with the eunuchoid voice. He considered this high-pitched, weak, effeminate voice that most of us are familiar with to be due to a simple malformation of the larynx, which a properly applied apparatus of compression causes to cease in a very short time. Dr. Kraus loses sight of those cases of atony of the vocal cords of nervous origin and as a sequence to diphtheria, which no amount of compression has any effect upon, the remedies indicated being electricity and massage: even these are too often of no avail.

It was a meeting of apparatus, this reunion of the Academy of Medicine during the last days of the old year.

Drs. Gilles de la Tourette, Chipault, and Gashe, took up the question of true elongation of the spinal cord by mechanism, from which it appears real services are thus rendered in a large number of cases of locomotor ataxia. Finally, Dr. Heide presented an apparatus for buccal prosthesis, which remedies in an astonishing manner an enormous loss of substance comprising the palate or the cartilage of the septum with sinking in of the nose. Dr. Heide is professor at the dental school.

As a fitting end to this mechanical sitting, Dr. Lucas Championnière spoke about a case very much in point, and adduced it to defend a doctrine that appears to be a favorite one of his. I refer to the treatment of fractures by massage. Massage, although chiefly of manual application, is also done by means of certain instruments and appliances, and may therefore be properly classed as a mechanism. Massage, according to Dr. Lucas Championnière, has given the death blow to the time-honored treatment of fractures by immobilization. Although Drs. Péan and Labbé made some restrictions regarding cases and the actual application of massage in the treatment of fractures, they recognized all the merits of this invention, which, in so far as my personal experience and observation of it goes, will prove to be one of the most ingenious discoveries in the domain of surgery.

Among the principal works presented to the academy were the new book of Dr. Henri Monod on "Public Hygiene," an instructive essay on hygiene, ancient and modern; and the "Treatise on Microbiology," by M. Duclaux, of the Pasteur Institut, which is really a model of its kind, and may truly be called an historical and critical *chef d'œuvre*.

Uterine Injections.—The nurse may be intrusted to administer vaginal injections, but uterine injections should be given by the physician himself. PARVIN.

MOVEMENT OF BOWELS AFTER OPERATION.

To the Editor of the Medical Record.

Sir: My remarks at the January meeting of the Medico-Surgical Society have been somewhat erroneously or rather insufficiently reported in your last issue. The subject being one of some importance, I should not like to go on record as having made exactly the statements attributed to me.

I did say that after operative interference with the intestines themselves I always give opium. If the small intestine has been dealt with and an exact approximation of peritoneal surfaces has been possible, I see no object in further continuing the administration of the drug beyond a few days. But if we resect the large intestine and suture parts of the bowel that have no peritoneal investment (mesocolon), I believe the bowels should be kept quiet, in the interests of complete union, as long as possible, as I have seen leakage on the tenth day.

When I have opened intraperitoneal abscesses, not adherent to the anterior abdominal wall, I pack with gauze and open the bowels no sooner than the fifth day, when I trust fairly firm adhesions have formed. But I do not give opium in these cases.

In clean abdominal sections I open the bowels on the third day, and I do not hesitate to administer morphine if required. F. Kammerer, M.D.

January 22, 1898.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 22, 1898:

	Cases.	Deaths.
Tuberculosis	241	94
Typhoid fever	7	1
Scarlet fever	210	23
Measles	361	16
Diphtheria	180	15
Laryngeal diphtheria (croup)	7	0
Chicken-pox	31	0
Cerebro-spinal meningitis	1	1
Pertussis	6	0
Parotiditis	2	0
Erysipelas	3	0

Ex-Ring Therapeutics threaten to outdo x-ray medication, and the solar plexus seems destined to have a greater influence upon the science of cure than the solar spectrum has ever had. An aggravated dyspepsia from which Mr. Corbett suffered prior to the receipt of the prostrating plexus punch has disappeared since that very date, and the cure is now attributed by the patient himself to Dr. Fitzsimmons. The frequency with which the treatment has since been tried by others, according to newspaper reports, must have impressed the public as noteworthy, but the mortality attending the shock would tend to render the average dyspeptic cautious about undertaking the cure. It might be well in this instance to resort at first to homœopathy, and take the medicine in small and mild doses.

Spread of Tuberculosis by Meat and Milk in Great Britain.—*The Lancet* says, in relation to the subject: "During a considerable part of the year a royal commission has been sitting to report on the administrative measures which should be adopted to control the spread of tuberculosis through the use by man of meat and milk as articles of diet, and we learn at the last moment that a considerable portion of the final report has been discussed by the commission, which is expected to report finally early in the ensuing session of Parliament. Perhaps the two most pressing matters to be dealt with are, first, how best to prevent the milk supply of our child population from serving as a means for conveying tuberculosis; and secondly, how far the demand for compensation for carcasses and for milch cows seized because they are tuberculous is to be conceded to butchers and dairymen. On these two points it is to be hoped a very definite opinion will be expressed."

Neurasthenia may be called forth in an individual suitably predisposed by active life with its modern needs on any pretext—over-exertion, excesses, trauma, constitutional diseases, acute and chronic infections, syphilis, intoxications.—Binswanger.

Eclamptic Albumin.—After examining three women in eclampsia Drs. Bar, Meun, and Mercier have concluded (*La Méd. Mod.*, December 8, 1897) that the urine in eclampsia contains an albumin which differs from other varieties, in that even in large amount it is wholly soluble, or so in great measure, in the presence of a minute quantity of acetic acid. This peculiarity is noted especially at the moment of access or in the premonitory period. The proportion gradually diminishes and finally the albumin disappears wholly.

Pulmonary Anthrax.—An instance is reported by Petrov, in which, without skin lesions or other signs of anthrax infection, death occurred upon the fifth day, after symptoms of chilliness, pain in the side, and shortness of breath. The autopsy revealed an abundance of anthrax bacilli in the pulmonary lymphatics. —*Archives Russe de Neurologie*, No. 32, 1897.

Health Reports.—The following statistics concerning yellow fever, cholera, plague, and small-pox have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended January 22, 1898:

Yellow Fever—United States.

		Cases.	Deaths.
Mississippi, Edwards	January 20th	1	

Yellow Fever—Foreign.

Brazil, Bahia	December 27th	3	2
Ceara	November 1st to 30th	..	1
Para	December 26th to January 21st	..	9
Cuba, Havana	January 7th to 13th	4	
Manzanillo	December 15th to 31st	..	7
Jamaica, Kingston	December 11th to January 1st	1	2
Manchester	December 11th to January 1st	1	1
St. Andrew	December 11th to January 1st	1	1
St. Catherine	December 11th to January 1st	1	
St. Elizabeth	December 11th to January 1st	1	1

Cholera—Foreign.

India, Bombay	December 7th to 21st	..	9
Calcutta	November 28th to December 11th.	..	23
Madras	December 4th to 10th	..	5
Singapore	November 1st to 30th	..	1

Plague—Foreign.

India, Bombay	December 7th to 21st	..	253

Small-Pox—United States.

Alabama, Birmingham	January 20th—Small-pox epidemic.		
Georgia, Atlanta	January 17th	131	now under treatment.
	January 18th to 20th	6	
North Carolina, New Hanover County	January 14th	1	
South Carolina, Swansea	January 15th—Small-pox reported.		

Small-Pox—Foreign.

Bohemia, Prague	December 19th to 28th	10	
Cuba, Havana	January 7th to 13th	12	
Sagua la Grande	December 25th to January 8th	70	8
England, Sunderland	December 15th to January 1st	1	
Gibraltar	December 27th to January 2d	1	
India, Madras	December 4th to 10th	1	
Netherlands, Amsterdam	January 2d to 8th	1	
Russia, Odessa	December 26th to January 1st	10	1
Warsaw	December 19th to 25th	..	5
Scotland, Glasgow	December 19th to 25th	1	1
Spain, Barcelona	October 1st to 31st	..	6
Wales, Cardiff	December 17th to 24th	..	1

GENERAL PARESIS—REMARKS ON ITS PRESENT-DAY CLINICAL DELINEATION.[1]

BY JOSEPH COLLINS, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE CITY HOSPITAL; ATTENDING PHYSICIAN TO ST. MARK'S HOSPITAL; NEUROLOGIST TO THE POST-GRADUATE HOSPITAL, AND TO THE ST. JOHN'S GUILD HOSPITAL FOR SICK CHILDREN.

Statement of Fact.—Every one who sees much of general paresis must admit that the clinical features of the disease to-day are not the same as they were twenty-five years ago, and that the majority of cases do not conform in their symptomatic features to the descriptions given in the books. Such symptomatic transformation is not exceptional in diseases of the less highly specialized systems of the body; typhoid fever, for instance, differs materially to-day in the way it unfolds itself from that seen by Gerhard, of Philadelphia, and Jackson, of Boston, who were the first to describe that disease in this country. When the nervous system becomes disordered in such a way as to constitute a definite disease, however, the symptoms that accompany are rather constant. In fact, general paresis would seem to be the only organic disease of the nervous system known, let us say to the previous generation of writers, that requires a re-statement of the symptoms.

Early Notions of General Paresis.—When the disease which is known as paresis, general paralysis of the insane, paretic or paralytic dementia, was first described by Haslem, Perfect, Esquirol, and other clinicians writing at the end of the eighteenth century and in the beginning of the century now waning, the motor paretic manifestations which are to-day the pathognomonic features of the disease were thought to be dependent upon some pathological process complicating acute mania or other form of insanity. It was not until Parachappe, and indeed before him Boyle and others of the school of French alienists, successfully combated this view and showed that the symptoms, mental and bodily, were dependent upon definite lesions of the central nervous system, and constituted a distinct form of insanity, that the disease was recognized as an individual one. When it came to be understood that the motor symptoms and the progressive mental decay formed a pathological and clinical entity, a detailed enumeration of the physical and psychical symptoms constituted the clinical delineation of the disease. Soon, however, one symptomatic concomitant of the disease seemed to become so prominent that it towered above the others. The feature to which I refer was the expansiveness of the patient's delusions and the exaltation of his waning ideas. So important a place did they come to occupy in the clinical descriptions of paresis that one readily infers from reading these descriptions that the disease did not exist without this delirium of grandeur, or megalomania, as it has been called, and, if it did, such cases might be looked upon as atypical or aberrant forms of the disease.

The Signature General Paresis.—General paresis, although a distinct clinical and pathological entity, reveals itself in a number of different ways, and it is quite impossible to describe the features of one or two cases and endeavor to maintain that all succeeding cases will parallel them. Nevertheless, the disease has, it matters not what clinical forms it assumes, certain definite bodily accompaniments which constitute the signature general paresis. These symptoms or physical signs are by far more important in suggesting or showing the presence of the disease, even in the earliest stages, than are the mental symptoms. Not that it is at all novel to mention or discuss these physical symptoms in general paresis, for they have always been recognized, but the mental symptoms have been given such undue prominence by the majority of writers on psychiatry that the former are not given due weight by the general practitioner. I have been a physician a sufficient number of years to have witnessed a change in the character and development of the symptoms of this disease, and the experience of each succeeding year convinces me that the form of general paresis described by writers on psychiatry as the typical, I might say the pathognomonic one is becoming less common, while the motor type, if I may so designate the form to which I ask your attention, is becoming more evident.

Symptoms of General Paresis, as Usually Given.—The symptoms of general paresis are divided usually by systematic writers into three or four stages, the customary division being into a prodromal or early state, an acute stage, and a terminal stage, each of these of from one to two years' duration. As portrayed in text-books the development of symptoms is somewhat as follows: The prodromal stage is attended and characterized by alteration of the patient's character and judgment; a perversion of his disposition, of his sentiment, of his probity—in brief, of his mental integrity; and by a progressive diminution of physical strength. It is oftentimes difficult to say wherein the patient has changed mentally, so slight is the alteration in the beginning and so insidious the onset. He may show it by intolerance of the ordinary harassments of life, forgetfulness of customary social and family amenities, by the habitual elaboration of commonplace incident or occurrence, or by indulgence in business transactions not fortified by good judgment. Or his mental derangement may be manifest by a selfish indifference to most pressing personal and family entailments, by a heedlessness of customary conventionalities, by indulgence in generosity and purchases incompatible with his financial status, or by perversions and brutal indulgences of sexual desires.

The second stage sees a continuance of all these symptoms and is accompanied even at the beginning by a remarkable degree of eupathy. The patient, although brought even at this stage by his mental infirmity to a cessation of his customary duties as a member of society and as a factor in the community, and robbed of the capacity legitimately to care for himself or those dependent upon him, is nevertheless filled with an immeasurable and boundless feeling

[1] Read before the Bridgeport Medical Society, December 7, 1897.

of his own importance, of his possessions, of his capacity to conquer and maintain, of his irresistibility—in short, of the Alexandrian feeling that the world, its denizens and its possessions, have been conquered. More than this, he professes the capacity to enjoy, to revel in, to extract the supremest pleasure from his talents and all that they have compelled. Unlike Alexander, he harbors not for a moment the querulous, sentient feeling of unhappiness in having no more worlds to conquer. Nothing is needed to complete his euphoria. His cup of bliss is overflowing, and he fears not lest it be overturned, for the conviction is full upon him that it could be easily righted and refilled. He distributes with a liberal hand; he is astonished that his generosity should excite comment; and he considers it unwarrantable infringement upon his personal liberty if an attempt is made to stay his hand by word or deed. He enjoys the astonishment which his purchases or his attempted business transactions cause. Everything is done on a magnificent scale in keeping with his colossal egotism, vanity, and manner. This is the stage of megalomania which writers have described so carefully, and which every one who has had to do with paresis recognizes as a mirror held up to the mental features of an uncertain number of cases. This stage is of course attended, as well as are the preceding one and the stage about to be described, by the presence and development of other symptoms, particularly motor symptoms, but I shall not attempt an enumeration of them, for they form the most important features of the disease as it unfolds itself to-day.

The third stage, the stage of dementia, the stage of rapid and complete mental decay, sees the patient at the beginning in the possession of that euphoria previously mentioned, but it is shrinking fast and there is becoming ever more manifest diminution of mental reaction and dissociation of mental components. These gradually extend until the mind becomes as blank as it was before the first neural constituents of the brain became medullated and functionable.

Motor Type of Paresis Occurs in Majority of Cases at Present Day.—I recall in my earlier experience many such cases of general paresis, and descriptions of them, as I have already said, are to be found in all text-books of mental diseases. That they are becoming less common may be evidenced to you by the fact that in the last three years, during which time I have seen thirty-one cases of general paresis, less than one-third of that number, viz., ten, have had any expansive delusions or exalted ideas whatsoever.

That you may address your attention more closely to the clinical form of general paresis that was in bygone years the common variety, I shall cite one example seen seven years ago, and which is most typical of the form characterized by delirium of grandeur. It may better portray perhaps the *tout ensemble* of this variety of alienation than would a long detailed clinical description.

G. D——, forty-three years old, an American, was brought to me by a brother in the autumn of 1890. He had reduced himself by dissipation and excesses of all kinds, from a desirable commercial position to that of a dependant and a vagrant. Twenty-three years before I saw him he was treated for the primary lesion of syphilis. The kind and duration of the treatment he received I am unaware of. His habits and indulgences had in later years ostracized him from his family, so that they were unable to give much information concerning the early symptoms of his present disease. He had been restored to them through the medium of a police court, where he attracted a great deal of attention by his asseveration of his personal worth and the persistent reiteration of his enormous possessions. On being rescued by his brother, he was quite devoid of chagrin or contrition, and continued to talk of his wealth, of his estate, and of his personal commendatory possessions, quite unconscious of the lamentable incongruity between his assertions and his real state. He was very forgetful, absolutely heedless at one minute of what he had said, done, or promised the minute before; easily excited and prompted to boisterousness; apparently devoid of either desire or necessity for sleep, and maintaining what appeared to be a superabundance of animal spirits, although getting very little of either of these restorers in the customary or habitual way. In other words, unless compelled to, he would go for long intervals without eating, and then eat ravenously and gluttonously, and it was the same about sleep. Although he would not sleep at night, he might sink into the slumber of exhaustion even while boasting of his millions and his "oceans of gold." When I saw him he had the striking and characteristic motor accompaniments of general paresis, viz., the spluttering, stumbling, inco-ordinate speech; the tremor of the facial and buccal musculature; the unsteady gait and tremulous hand; the unequal, stiff pupils; the exaggeration of the knee jerks; in short, the motor accompaniments which constitute the signature general paresis. His delirium of grandeur was evidenced from the moment of his entry, which was one indicative of an exalted personage condescending to favor a fellow-being with his presence. But there was no reserve in the condescension. He told me in the most matter-of-fact yet eager way of his intellectual possessions and personal adornments. He was not adverse to letting me know that they had both caused him to be much sought after. His capacity to do, to execute, was limitless. Slight reference to his financial status provoked the offer of $100,000 as a loan or a gift; either disposition was apparently of equal pleasure to him. His estate encompassed a large part of the State of New Jersey, and its arrangement and disposition were in keeping with its size. The most constant assertion in regard to his wealth, however, was that he had "oceans of gold." Prompt his thoughts to any fancied possessions, and he would dilate upon them in the most expansive way. He was particularly proud of his procreative organs and of his fertilizing capacity. Not only the size of the former but the ease with which he had fathered more than a hundred children were spoken of with evident pride and satisfaction.

I had opportunity of studying this patient to the time of his death, and it would be but a repetition of the symptomatic features above hinted at, if not mentioned, to describe the change and evolution of his symptoms to the ending. The dementia, which was well pronounced when I first saw him, increased week by week; the somatic accompaniments of the disease, particularly the inco-ordination as manifest by defective speech, became more striking; the physical strength gradually ebbed away. But even to the very end of speech capacity, at a time when the last vestige of similarity of words had departed, I could still discern in the lalling which replaced articulate speech the ghost of the phrase, "oceans of gold," almost automatic and like an echo. He died about two years after I first saw him. A few months before death he became completely bedridden, the four extremities paretic, the functions of the bowels and bladder almost derelict, the swallowing capacity seriously impaired, and finally he died under the auspices of an attack of hiccough.

Cases of this kind could be duplicated from my histories, but I have selected the one most typical of them. It has astonished me that I saw them in the earlier years of my interest in neurology and that during the past few years I have encountered them more rarely, although naturally the opportunity for seeing cases of general paresis has been more abundant.

This experience has impressed upon me the justification of the title of this paper. Moreover, I embraced the opportunity which was given to me during the past summer to talk with some of those to whom we are indebted for much of our knowledge of the nature and history of this disease, such for instance as Mendel, and was much gratified to learn that the same opinion or conviction was shared by them.

The Present-Day Type of Paresis.—The type of general paresis which I encounter most frequently today is one that conforms more closely to the original descriptions of the disease before the time that the expansiveness of the patient's delusion and the exaltation of his ideas were made such an important integral part of the clinical picture. In other words, the prominent symptoms of by far the majority of cases that have been recently under personal observation may be summed up in a few words. They are the predominance of what we may call the somatic symptoms, viz., the pupillary symptoms—stiff, rigid, unequal pupils; the facial tremor and the emotional reflex; the changes in speech, which are by far the most striking and diagnostically the most important; the disordered handwriting; the alterations of knee jerks; the manifestations of inco-ordinate muscular activity; the spasms and the paresis, on the one hand; and by progressive dementia on the other: a progressive failure of all the components of intellectuality, beginning with the highest and most developed, and ending with those which may be called the result of activity beneath the threshold of consciousness, and extending to embrace those almost reflex and automatic. To bear me out in these assertions, I shall cite a few unselected cases, taken mostly from my records of private cases, for it is in this kind of practice that one has opportunity to study his cases most satisfactorily. There he may witness the phenomena attending the onset of the disease and study the early manifestations of it with the patient, while sufficient mind is still vouchsafed the victim to make his statements credible.

Case I.—Mr. X——, forty-four years old, a banker, married, the father of two healthy children. He denies syphilis. He did not marry until his thirty-third year, but nevertheless he and his family say that he had been a temperate man. Since then he has smoked excessively and has been a steady drinker, oftentimes indulging too freely. He was never an intellectual or a sociable man—retiring, non-communicative, of no considerable mental ability; an unnoticeable man. He dates his ill health back only a few months, but on close inquiry he says that it is at least seven or eight years since he was perfectly well. The first symptoms seem to have been unaccountable fugitive pains in different parts of the body. At one time there would be a painful area no larger than the end of a finger or as large as a silver dollar on one arm or the other, in one thigh, in the neck, and in different parts of the body. These pains were not lightning-like pains; they were not traceable to any cause; they would come and go suddenly, and the only accompaniment or sequence was a sore feeling where they had been manifest. He says that at this time a physician whom he consulted noticed an irregularity of the pupils, and that one of them did not retract to light. These pains continued for a few years, sometimes causing much complaint, at other times little, and later there were added frequent cramps in the legs at night and a restlessness of which he was not cognizant. Three years before coming to me he consulted Dr. Noyes at the request of his physician, who noted: "There is paralysis of the pupil and accommodation of the right eye, together with an affection of some other twigs of the third nerve which is obscure and which I cannot make out with exactness, on account of the indefiniteness of the symptoms. The latter, however, point to spinal sclerosis. He denies syphilis, but he has had it."

When he consulted me, the story was that he had fulfilled the offices of cashier in a banking establishment until three months before, but for the past year or two the patient's family has noticed that he was gradually becoming changed. Formerly he took a lively interest in his personal appearance, but latterly this has been very much neglected. He has lost interest in his children and affection for his wife. He has no particular inclination or desire for anything that is proposed, either for his amusement or for his advantage. Although he reads the papers he does it in a perfunctory sort of a way, and it is apparent that he absorbs neither what he reads nor what he hears. He is inclined to talk of incidents and happenings of twenty years ago, and to go over them even to the most unimportant and uninteresting details, to the great fatigue of his hearers. For recent events he manifests decided aversion, is unconcerned and forgetful of them. When asked a simple question requiring for its answer slight mental activity, he puts off his interlocutor with an evasive reply. Yet oftentimes he amuses by *à propos* comments and more or less humorous sallies. Perhaps it should be said that his most developed possession when normal was a keen sense of humor. He avers that he is quite well except that he has cramps in the calves of the legs and pains in the extremities, which he calls rheumatism. He becomes fatigued very easily, sleeps badly, and is extremely restless at night. This restlessness or agitation persists during sleep, and in reality it would seem to be a convulsive movement of the extremities; a quick, short drawing up of the legs and arms and then a shooting out of them, followed by relaxation.

An examination of this patient shows practically the same condition of the eyes as reported above by Dr. Noyes, but in addition it is seen that there is no response to light in the left pupil. There is decided tremor in the facial and buccal musculature, especially marked immediately preceding an effort at speech, and preceding emotional display. Speech is stammering, word production indistinct; the consonants are elided or left out, and when he attempts to say complicated words, such as "incompatibility," "artillery," "rural intelligencer," the result is a mixture of vowels blended with aborted consonant sounds, the whole being quite unintelligible. The diction itself is disturbed: oftentimes the patient uses incorrect words and constructs ungrammatical sentences, and very frequently is at entire loss for a word. There is pronounced tremor of the hands, which is very manifest in writing. The knee jerks are exaggerated and the station and gait are uncertain, although there is no real ataxia. The patient still controls the urine and bowels, and says that the sexual functions are unimpaired; in fact, that there is a mild degree of satyriasis.

About a month after I first saw him he began to complain of stiff neck, and of increased restlessness at night, and of slight exacerbations of all the symptoms. The dementia, which was manifest at his first visit in his being unable to tell me the street in which his wife had recently purchased a house, to tell me what he had had for breakfast that morning, to compute correctly six times eight plus one, and to answer a number of equally simple and easy requests, was continually becoming more apparent. He became weaker physically and complained of the stiffness and pain in the neck. Shortly after this he had one evening, while walking to the bathroom, a typical epileptic attack: universal twitching, frothing at the mouth, biting of the tongue, and loss of consciousness. When he recovered consciousness he acted as if nothing had happened, and there was no immediate paralysis. He

told me that he did not recall having had an attack of any kind. The next morning, however, the left upper extremity was somewhat flaccid. During the next two or three days he had several epileptoid convulsions. At night the evidences of motorial irritability manifesting itself by short, sharp jerks of the extremities, very much like the twitch of a tic or an electric shock, occurred during sleep. A few days after this the right upper extremity became paretic, and later still the lower extremities became flexed, and when one made an effort to extend them there was involuntary and forceful resistance, and the patient would cry out as if it gave him great pain. There was a considerable difficulty in swallowing, and hiccough was occasionally a very annoying symptom; and the patient had a sinking sensation, a feeling as if he were falling off the pillow and off the bed: a symptom that may best be interpreted, I think, if we look upon it as a vertigo occurring to one in the reclining posture. The patient had to be catheterized, but there was no incontinence of urine and fæces. There had been no delusion of any kind from the beginning to the end of the disease. A few hours before his death he recited with childish enjoyment some experiences of a fishing-trip made in his youth, and talked until exhausted. He had no idea of the gravity of his condition, and was apparently quite indifferent to the occurrence of such ominous symptoms as palsy, first in one extremity and then in another, until all four were involved. He did not appreciate that he was on the threshold of dissolution, and joked with me about going out to eat a rarebit in the early hours of the morning that he died. The symptoms that had antedated death for a few days, in addition to those already mentioned, were difficulty in swallowing, paresis of the facial musculature, and progressive impairment of the muscular act of respiration—general paresis in the fullest sense of the term. Naturally, he had become more and more demented, but to the casual observer he would seem to have been of sound mind, even on the day of his death. Death occurred six months after he was compelled to relinquish business and about six years after the first manifestation of symptoms of the disease. The autopsy and microscopical study showed typical and characteristic changes of general paresis, and as I intend to report these in detail in another connection I shall make no further reference to them here.

I have described this case at some length because it illustrates the clinical type of general paresis which I am desirous of having you believe is continually becoming more common. Naturally, no two cases of the disease are alike, but this one may be taken as an example of the motor type—the type in which the physical symptoms are prominent and the psychical ones are in the background.

Another feature of general paresis that has impressed me very much is the attributed abruptness of the onset of the disease and the comparatively short time that elapses between the time of incapacity of the patient and the occurrence of death. It is not uncommon for patients or members of their families to fix a certain day, or even hour, when the symptoms appeared. This feature is well illustrated by Case III., and it, as well as absence of conspicuous mental symptoms, is shown by the following histories:

Case II.—A. H——, an unmarried man, thirty-one years old, occupied as a clerk in the comptroller's office in New York, was brought to me by his mother, January 16, 1895. He sprang from sturdy ancestors, and so far as could be learned he had led a moderately temperate, uneventful life. He had been fond of outdoor sports, but did not care particularly for society or social dissipations. As a boy and young man he was bright and active, and of a cheerful disposition. He denied syphilis, although he was in a mental condition to inspire no trust in his statements. He attributed his sickness to women, but it was impossible to get from him any statement as to how the weaker sex had injured him. His mother declares that he was quite well and attentive to business until three weeks before his visit to me. The first noticeable change was a suddenly developed reticence and a desire to be left alone. Without apparent cause or word of explanation he remained at home one day, moped about the house, and after that refused to go out. When urged to do so he made incoherent or unsatisfactory answers. He became extremely nervous, and it was remarked that speech was becoming stumbling and difficult to understand. He lost all interest in his personal appearance and in his family, and became apparently an element in, but without distinct relationship to, his surroundings.

When I examined him the most striking objective features were inequal and immobile pupils; expressionless, sluggish countenance; tremor of the face and tongue, more marked preceding emotional display and attempts at speaking, but also present when the patient was quiet. Stammering, almost unintelligible speech; tremulousness of the extremities so great that he could scarcely write his own name; exaggeration of the knee jerks, and a wobbling gait of weakness. Mentally, he was much demented, but apparently had no delusions. There was no exaltation, no self-satisfaction, no boastfulness or display. He was sent to a private sanatorium where he steadily grew worse, and died eight months from the time that he relinquished his position, having become completely paralyzed some weeks before death.

Case III.—C. S——, thirty-nine years old, a merchant, seen with Dr. Powell, November 1, 1897. He is married and his wife has had one child and three miscarriages. Specific infection is denied, but he is not in a mental condition to have credence given to his statements. He has been a strong, healthy man and has had only trivial illnesses. The history obtained from his wife is that he was well and attended to his business until two weeks before I saw him. On the morning of that day he was sitting at the breakfast table when he complained of feeling dizzy and of seeing double, and she noticed that his eyes were not straight. After this his complaint was of headache and of dizziness, but he did not complain very much. The principal symptoms that followed immediately after this were loss of memory, crying-spells occurring without apparent cause and without justification, silly snickering and causeless laughter, thickness and jumbling of speech, restlessness and jactitation. Careful and repeated inquiry reveals the fact that although the disease manifested itself in this abrupt fashion, in reality the beginning of it can be traced back three years, when it was remarked by his family that he was not looking after his business with his customary interest and ability. It is also recalled that his memory had been ailing for at least this length of time, and that he acted a bit odd, confused, preoccupied; indulged in day dreaming, and made some complaint of occipital and vertical headache. He engaged in some business transactions the outcome of which did not redound to his credit, but notwithstanding all this he kept to his business with a good deal of regularity, and his wife avers that she noticed no change in speech until the onset mentioned above.

Examination shows a poorly nourished man, who bursts into tears when I ask him his name. The pupils are irregular and do not respond to light and shadow; the countenance is vacuous; the face is the seat of tremor, especially preceding emotional display; there is inability to whistle; speech is very defective, sputtering, and indistinct, quite pathognomonic of general paresis. There is such marked tre-

mor of the hands that the patient can scarcely sign his own name, even if the physical weakness were not so great as nearly to incapacitate him, as it is. The knee jerks are exaggerated and attempts at standing and walking are abortive, owing to weakness and inco-ordination. Memory is almost effaced: he makes no request or complaint, has no delusions of any kind so far as can be determined; he is demented and becoming more so every day. Dissolution went on progressively, and the end came six weeks from the day that he gave over attendance on his customers. The immediate antecedent phenomena of death had been those of universal paralysis.

The next case is one of a somewhat different clinical type, but nevertheless distinctly "motor." It is one often duplicated in my experience.

Case IV.—E. A——, thirty-seven years old, seen with Dr. C. S. Eleabash, April 9, 1896. He is a temperate man, has been married eight years and is the father of four healthy children. He has never been ill except with what he calls "nerve fever," which he had when twelve years old. He and his family date his illness to the occurrence of varicose veins of the leg which ulcerated, in the summer of 1895. As the result of this he lost considerable blood and became weak. He kept at his work, however. In August of the same year he had a convulsive attack, of which it is difficult to get a clear account, which was followed by transitory left-side hemiplegia and impairment of speech. After this it was remarked that he was weakening in bodily and mental strength. Speech began to be altered, memory became unreliable; he lost his position, to all of which he seemed to be quite indifferent. One of the earliest symptoms in this man's mental impairment was difficulty in finding his way back to Brooklyn after his work was done. Occasionally he would get over to Jersey City or Staten Island instead of taking the ferry to Brooklyn. There have been no delusions, no exaltations: simply a mere indifference, a lack of interest, no matter what predicament he finds himself in.

Examination shows irregular myosis of both pupils, the left slightly larger than the right, and both inactive to light and darkness; marked tremulousness of the face and tongue, but not of the extremities: speech sputtering, indistinct, and jumbled. When he is excited or emotional it is quite impossible to understand him. The voice is tremulous and interrupted and of uniform intonation. The knee jerks are enfeebled, the pulse is small, the extremities are cold, and the digestive apparatus is disordered. The gait is uncertain and is like that of one suffering from bodily weakness. The memory is very unreliable; he has no interest in his family or in himself; ordinary family amenities are no longer recognized, and he does many things which a scrupulous father and husband would blush to do. In the past four months he has had three convulsive attacks, and after each one it has been noticed that he is more nervous, less dextrous in the use of the hands, less agile on the feet, and weaker mentally. He died in an asylum one year after I saw him.

The next case is one of considerable interest because the traumatic origin of the disease is clearly apparent, and because the case is said to have been diagnosticated by a neurologist as one of brain tumor.

Case V.—J. D——, an employee of the elevated railway, forty-seven years old, was seen with Dr. James Moran on the 9th of February, 1896. The patient's history previous to the onset of his present illness was that formerly he drank a good deal, and that he never had syphilis. In fact he declared that he never had sexual intercourse until after marriage, which event occurred in his forty-second year. His wife has borne three children and has had two miscarriages. Three years and seven months before I saw him he was struck on the right side of the head by a falling weight. He was not made unconscious. He went to the hospital to have the wound dressed, and its extensiveness is indicated by the fact that the surgeon gave him ether. He was laid up about a fortnight as the result of this accident. Then after a week or so longer he returned to work and stayed at work until four weeks before I saw him. When I asked him why he gave up his position, he answered in a tremulous voice and with disordered articulation:

"I'd lose everything that I'd be doing: I don't know how to use my tools any more. I take hold of them and then don't know what to do with them."

"You do not mean to tell me that you pick up a familiar tool and wonder what it is for?"

"Yes, and if I should leave it down out of my hand for a moment, I would not know where it was, and when I am looking for it I do not know what it looks like." (A condition known as apraxia.)

When the patient was asked what he complained of, he said:

"I am dizzy occasionally: I used to think there was a tight band around my head, especially over the forehead and eyes: and now I have headache, most on the left side, and a feeling in the top of the head as if there were small shot kernels in there."

Although it will be noted that the patient says he kept at his work until four weeks ago, close inquiry reveals that symptoms of his disease have been noticed for at least two years and perhaps longer. His wife states on being questioned that she remarked a thickness and uncertainty in the patient's speech about one year after the injury. She says, moreover, that he has been extremely irritable, very excitable, and easily aroused to manifestations of temper or emotion. She also recalls that as far back as three years ago there were periods when he staggered very much the same as if he were under the influence of liquor, but that he has not staggered much since then until lately. Perhaps the most suggestive statement that she makes is that the patient has had what she calls "attacks," during which his speech would become worse, tremulousness of the hands well marked, and uncertainty in locomotion very evident. For the past two years, she says, he has been getting forgetful, querulous, and devoid of interest in his family and surroundings. Two or three times he has lost himself. About four weeks ago he went to a church in the neighborhood, one to which he had been accustomed to going, and he could not find his way back home. He passed through the street in which he lived, apparently saw the house, but he could not be convinced that he lived there. He maintained stoutly that his house was on the other side of the street. Another time he started down town on an elevated train, intending to get off at Franklin Street, but he got off at some other station and could not orient himself, and it was with great difficulty that he was got back home. Latterly he is not allowed to go abroad alone, on account of this difficulty in getting back. When at home he sits about all day, oftentimes apparently engrossed with a paper or with a book, which he appears to read, although he rarely turns a page. He may be poring over the print as if he were very much interested. He says he understands what he reads when he reads it, but he cannot understand it afterward, which on being interpreted probably means that the letters and words are still recognizable. He has apparently had no delusions, although his wife says that during the beginning of the present attack he spoke about taking a trip to Europe for the benefit of his health, and when she pointed out that although this would be a very commendable performance it was scarcely possible without some funds, he replied that he had plenty of

money and could go very easily if he so desired. When I questioned him about this, he said that if he had had such ideas they were delusions, and that he had none of them now. At times he has been so forgetful that he would start to undress at bedtime and forget to take off the most essential part of his clothes, such as his shoes.

Examination shows a well-dressed and apparently well-groomed man. His wife says that formerly he was extremely careful of his appearance, but that now she has to look out for it. When the patient speaks the voice is unsteady, there are a slurring of the words and an indistinctness of articulation due to elision of the syllables and incomplete pronunciation of the consonants, and explosiveness of the sounds and lack of uniformity in the tone, all of which simulates the speech of an intoxicated person. The pupils are irregular, the right is larger than the left, but the right does not respond to light, while the left does somewhat. The knee jerks are exaggerated and there is a pseudo-patellar clonus. He causes a very stiff dynamometer to register 85 with the right hand and 90 with the left. (The patient I might say was a right-handed man.) He still possesses a degree of sexual potency, and there is no dereliction of either sphincter. There was no particular tremor of the hand at the time of this examination. Mentally the patient is incapable of attention or connected thought, and although he answers questions rationally he very soon becomes fatigued and loses interest. Lately he has been praying a good deal and has a desire to go to church very often, but he can give no reason for such revival of religious interest. Just before he was sent to an asylum he had an epileptoid attack, and after that his mind became more disorganized and he died in an asylum a few months after I saw him. The course of the disease from that time on was typical of the terminal stage of general paresis.

The next case may serve to point the perniciousness of overwork in a syphilitic person.

Case VI.—P. I——, thirty-four years old, by occupation a piano maker, seen July 2, 1896. He is married, the father of two healthy children. His wife has had one miscarriage and one stillborn child. The family history is negative. Fourteen years ago the patient had a sore on the penis, followed by the customary secondary cutaneous and mucous-membrane manifestations. He was treated with some degree of regularity until the latter disappeared. Possibly he was under treatment for six months altogether. Eight months before he came to me his friends noticed for the first time that there was something wrong with the patient's speech, and that soon after this he lost the ability properly to control the extremities. The speech disturbances, however, they are sure were the initial and prominent condition. His family and friends attribute his illness to overwork. They say that until a few months before speech disturbance was first noticed he worked at his trade for upward of sixteen hours a day for more than three years. About six months after his disturbance of speech was first noticed he was obliged to forego his work because of tremor of the hand.

Examination of this patient revealed the stumbling, jerky, dysarthric speech, tremor of the tongue and of the lips, slight exaggeration of the knee jerks, slight impairment of station and locomotion, impaired smell and taste, marked tremor of the hand, and some cutaneous anæsthesia. The pupils maintained a slight response to light, but they were comparatively sluggish. In other words the somatic symptoms were monotonously those of general paresis. The mental symptoms which the patient had had may be summed up in a line: Progressive dementia and uniform feeling of well being. About three months after I first saw him he had his first epileptiform attack, and following this a transitory left-side hemiplegia. After this he was mentally and physically much worse than before, and soon after had to be sent to an asylum, where he now is in the terminal stage of the disease.

I shall not take up more of your time in relating histories of cases of this disease. Those that I have spoken of may be taken as fair examples of a great number that I might detail.

The Variability of the Mental Symptoms and the Invariability of the Physical Signs.—Naturally, the complexity of the symptoms constituting general paresis varies with almost every case, but no disease with which I am acquainted has such invariable diagnostic features as the one under discussion; and although the statements that one gets from different patients and their families will seem on casual hearing or reading to be quite unlike, when they are examined carefully and analyzed it is plainly evident that victims of general paresis have certain unfailing somatic symptoms which were alluded to in the beginning of this paper, and which have often been repeated in the enumeration of the symptoms of the cases reported herewith. The psychical symptoms are the variable ones in reality, but this should not astonish us when we consider the different types of mental reaction or the different types of mind that we continually encounter. It would be just as rational to expect that every man should think alike, have the same sentiments and emotions, as it would be to expect every man to have the same manifestations of mental dissolution when the brain is diseased.

Perhaps I have said enough to compel your attention to if not to convince you of the fact that general paresis is undergoing a clinical rehabilitation at the end of the nineteenth century. Naturally I do not mean to say that all cases of general paresis conform to the type of those above cited; no more do I wish to convey that I do not encounter cases that conform in every particular to those described in the books of a decade or two ago. I do meet such cases, and, as I have said, they constitute in my experience about thirty per cent. of the entire number. General paresis will probably continue to manifest itself in an uncertain proportion of cases by exalted mental states, delirium of grandeur and megalomania: but at the present day some unknown forces are at work shaping the human mind in such a way that those conditions and eupathy are not engendered when it undergoes that form of dissolution attending general paresis.

Causes of the Clinical Transformation of the Disease.—It is scarcely possible to do more than to hint at the probable causes of this clinical transformation. They may have to do with the pathologic process forming the anatomical basis of the disease, or they may be the consequence of latter-day variations in the occurrence of the disease. To pursue this statement further and illustrate what I mean: Formerly paresis was a comparatively rare disease, and, although it was described nearly a century ago, yet in the early part of the present century it was practically unknown. Even as late as 1867 it formed but one-sixth of all the insanities. But to-day it forms between one-fourth and one-third; in other words, during the last quarter of the present century its frequency of occurrence has been nearly doubled. Moreover, whereas even up to a short time ago the disease showed a special predilection for certain peoples, nowadays it is less selective and elective. Formerly paresis occurred almost exclusively in men, and, moreover, in men of the upper classes socially, intellectually, and financially. Nowadays it is often seen in women, the proportion being, according to the statistics of some countries, five to one, and in others two to one. But what is more surprising is that it

does not gather its female victims from the upper classes but from the lowest. Another point in the occurrence of general paresis that is worthy of consideration in an endeavor to interpret the change in the clinical features of the disease of which we have spoken is that to-day general paresis is recruiting its male victims more and more from the lower classes, and that it is seen with greater frequency in rural districts than it was in former years. It should not be forgotten, therefore, that the type of mind inherited or developed which undergoes disorganization to-day as the result of general paresis is materially different from that of twenty-five years ago. Moreover, the average age or time of life at which the disease develops is becoming every decade much less. Formerly it was about forty-three years, but to-day it is well down in the thirties, and it is not uncommon to encounter it in the twenties and even earlier.

When such a large number of all general paretics come from peoples of small intellectual possessions, it may be that the explanation for the change in the clinical picture is that the rudiments of expansiveness and exaltation of ambitions and conceits, never having been present in the normal mind, are not engendered when the mind disorganizes. On the other hand, the explanation may be that the morbid process has a different intensity or a different point of attack than formerly. It is a well-known fact that when cases of general paresis come to autopsy the lesions in the brain are of both cell and fibre, but in the beginning of the disease either the cell or the fibres must be first attacked. It has been taught by some pathologists that the cell is invariably the first to be affected, but this has not been demonstrated convincingly. If the brunt of the lesion were to be borne in the beginning by the motor cells of the Rolandic cortex and their axis-cylinder processes, the early manifestations of the disease would be predominantly motor, while if other cell bodies and their protoplasmic processes were the first to become disorganized the psychical and special symptoms would be in the foreground.

It is not probable that the attributable causative factors of general paresis have had anything to do with causing the clinical transformation, except in so far as they have been the cause of the racial, social, and sex distribution mentioned above. The causes of the disease to-day are the same as they were a decade or five decades ago. Syphilis, trauma, and excesses are the tripod upon which rests the genesis of the disease. All these have increased in frequency of occurrence latterly, and they are continuing to increase. Any one of them is sufficient apparently to cause the disease, but if the most potent one in conditioning general paresis, viz., syphilis, has added to it any one of the others, be it excess of alcohol, tobacco, sexual indulgence, overwork, or any other form of dissipation, or if such a patient is subjected to physical or mental trauma, the danger that such a patient will develop paresis is enormously increased. The disease is increasing, and, as Krafft-Ebing has truthfully said, its increase has been proportionate to "syphilization and civilization." Indirectly it may be that these causes have conditioned the change in the symptomatic accompaniments of the disease by rendering it less elective in its occurrence and less selective of its victims.

Perhaps the treatment of syphilis has had something to do with the clinical transformation of the disease but personally I am not inclined to such a view. The treatment of syphilis to-day does not differ materially from that of a quarter of a century ago, except that perhaps it is carried out more energetically and for a longer time, and it is difficult for me to see wherein this thoroughness of treatment can have any bearing on the change of symptoms in a disease which it conditions years after.

My object in this communication, however, has been to invite your attention to the disease as developed, and to hint only at the factors that develop it and the elements that shape its course.

47 West Thirty-Eighth Street.

IS SEXUAL NEURASTHENIA IN THE MALE AS FREQUENT AS IS COMMONLY SUPPOSED?[1]

BY EUGENE FULLER, M.D.,

PROFESSOR OF VENEREAL AND GENITO-URINARY SURGERY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING GENITO-URINARY SURGEON TO THE CITY HOSPITAL.

It would be out of place for me, accustomed to busy myself with genito-urinary questions, to present a paper before this section, composed of expert neurologists, with the idea of enlightening any of you on the subject of neurasthenia pure and simple; and if I were foolish enough to do so, I should fall as a result of your critical attack. I am therefore going to keep on safe ground, and if I provoke a quarrel with you it will be one simply over the distribution of professional spoils. The general practitioner in an able manner distributes a considerable portion of the patronage allotted to the special workers in medicine. He sometimes errs in sending a person to a wrong department. Most mistakes of this nature are, however, made by those who of their own knowledge select a medical adviser expert in some special line of work. In dealing with this latter class it devolves upon the specialist, if wrongly selected, to rectify the mistake; and in this connection I take the liberty of suggesting that a goodly proportion of the males who think themselves afflicted with sexual neurasthenia are in reality suffering from inflammatory disease of their sexual apparatus, their nervous symptoms being simply reflected from and dependent on such inflammation. In part proof of this assertion, I think I am safe in saying that there is no other class of patients presenting neurasthenic symptoms which the neurologist treats with less assurance in his own mind of benefiting than these. The reason for this is that he cures only such of them as are truly suffering from sexual neurasthenia, the treatment in the other instances being inappropriate, since it is not directed toward the seat of disease. I think it probable that many neurologists would criticise my last statement, by the assertion that a considerable percentage of the cases presenting the symptoms under consideration which they have failed to benefit has been sent to them by genito-urinary surgeons after they themselves had failed.

In my earlier years of practice I was forcibly impressed by the unsatisfactory general results with which these sufferers were treated. Still, on comparing the results obtained by neurological methods with those obtained by the genito-urinary surgeon, I must say that the neurologist had the advantage, since he cured some of his cases and did not aggravate the condition of the others, while the genito-urinary surgeon rarely cured any of his, unless perchance he borrowed his methods from the neurologist, and made matters worse for many of them. The reason why genito-urinary surgeons formerly aggravated the symptoms connected with many of these cases (and some of them, I am sorry to say, still persist in these methods) was because they sought to correct some supposedly causative lesion situated in the urinary tract—the fact that such a thing as a lesion in the genital apparatus could exist as a cause being completely ignored. With this end in view the urethra was vigorously stretched with

[1] Read before the section on neurology of the New York Academy of Medicine, December 17, 1897.

sounds, its deeper portion bathed by strong stimulating injections, or a stricture of large calibre found in the anterior portion and divided.

In true neurasthenia, no matter what the special features may be, the symptoms complained of arise from some functional disturbance in the nervous system itself; and if in a given case an organic lesion exists as the cause for the nervous symptoms, then that case is not one of neurasthenia. The diagnosis of neurasthenia in any instance, it seems to me, should be most carefully pronounced, for such a decision always means that the investigator has failed to find any tangible cause for the symptoms complained of, and so, as the result of a process of exclusion, has laid the blame on a disordered condition of the nerves themselves. Most patients accept such a diagnosis with reluctance and dissatisfaction, and if, on seeking further advice, a second investigator, more clever than the first, discovers some sufficient cause for the symptoms outside of the nervous system, then the one who has made the diagnosis of neurasthenia is apt to be blamed not only for his mistake, but especially for injuring the feelings of the patient by having insinuated, as it were, that the symptoms of complaint arose simply from the condition of the nerves—or, according to the patient's interpretation, were imaginary in character. I recall with feelings of pain, although the lesson it taught me was of value, a case occurring in my early years of practice, in which I made a diagnosis of facial neuralgia, the patient being a very gossipy young woman. After failing to get relief at my hands, she quietly consulted a dentist, who quickly and permanently relieved her by pulling a tooth.

If one systematically investigates his cases presenting symptoms sexually neurasthenic in character, he will generally find, first of all, that there is something wrong with the sexual act itself. If desire is abnormally great and persistent, satisfaction derived from the act is apt to be correspondingly slight. Desire may seem natural, but erections may be wanting. Of special importance, however, are irregularities in connection with the act of ejaculation. It may be very premature, although sometimes the opposite state of affairs may exist, it being long delayed and apparently largely beyond the control of the individual. It is often described as lacking in force, the volume of semen ejaculated frequently striking the individual as below normal, or it may be *nil*. Ejaculation may be painful at the time, or followed by pain, or it may arouse disagreeable localized sensations. In a few instances there is nothing apparently abnormal in this particular. In many cases it will be found that an attack of gonorrhœa apparently shortly antedates the period at which the symptoms complained of seem to have originated. At other times one may find a previous history of marked excess or abuse. There may be coincident urinary disturbances, such as a urethral discharge, pus or shreds in the urine, frequency in the act of urination, etc. Complaint may be made that semen is lost, possibly at stool, and the microscope may find it in the urine. Annoyance from emissions is not unusual. These may be frequent during sleep, and accompanied or followed by the same subjective symptoms which have been enumerated in connection with ejaculations during coitus. The material ejaculated may be bloody or purulent, but rarely excessive in amount. Then, again, it may be that emissions are described as occurring while the individual is awake, in spite of his will power and from no sufficient exciting cause. Although other symptoms indicative of derangement of the sexual apparatus might be enumerated, still the ones just cited are the commoner and are sufficient for illustration in this connection.

The numerous mental and nervous disturbances which may be the prominent feature in such cases as are representative of true neurasthenia, and in those in which the symptoms are simply dependent on disease of the sexual apparatus, need not be here detailed. The mental symptoms are usually of a melancholy character, associated with much lassitude and inability to apply one's self.

If, in a given instance, as a result of careful questioning, one finds evidence that the sexual function is itself more or less deranged, certain of the above-enumerated symptoms being present, and especially if there has coexisted in the history a preceding cause such as might tend to inflame the sexual apparatus—then in all probability the case is not one of neurasthenia, but of localized disease of the sexual apparatus. Such localized disease, to affect the active exercise of the sexual function, must lie in or about the seminal vesicles and their ejaculatory ducts. The positive diagnosis of morbid conditions in these parts can be determined by the sense of touch imparted to the tip of the forefinger, that member being introduced into the rectum so that its tip can pass over and press against the rectal wall covering the sexual organs just mentioned. If sufficient evidence of disease is so discovered in this region, then the idea that the case is one of sexual neurasthenia should be dismissed and a diagnosis of seminal vesiculitis made.

As the outcome of much investigation and study in this class of cases, I feel justified in asserting that out of twenty consecutive instances fully nineteen are on the average representative of seminal vesiculitis in some form to one of sexual neurasthenia.

It would be natural for some one to inquire at this juncture upon what I base my reasoning that neurasthenic symptoms are so frequently dependent on diseased conditions of the seminal vesicles. To such a query I would reply that I base it on the fact that the nervous and mental symptoms disappear as resolution in the seminal vesicles is effected, or, in case complete resolution cannot be effected, that these symptoms almost always disappear, provided the disease in the seminal vesicles can be so far ameliorated that the performance of the act of ejaculation can be accomplished without hindrance from a coagulated or catarrhal condition of the contents of the sacs, from atony or inflammatory rigidity of the sac walls, or from perivesicular inflammatory adhesions which bind down the seminal vesicles and render them immovable. If, also, as a result of the improvement due to treatment, the nervous and mental symptoms have largely disappeared in a given instance, there is almost always a speedy reappearance of these symptoms provided a relapse occurs in the morbid condition of the seminal vesicles, such relapse being due in most instances to indiscretions on the part of the patient or to the production by the surgeon of too great a reaction from overtreatment.

The physiology and pathology of the seminal vesicles, together with the methods of diagnosis and of treatment, which I take the credit of having in large measure developed, are fully detailed in my book, "Disorders of the Male Sexual Organs," and consequently need no reiteration in this connection.

One might suppose from what has been said that neurasthenic symptoms are necessarily associated with seminal vesiculitis. Such, however, is not the case. Very many individuals having localized disease of the part have no such symptoms, and it is only in a minority of them that nervous and mental disorders are prominent. Neither are these manifestations, when they do exist, evidence of the grade or extent of the seminal vesiculitis, since many times a moderate lesion may be accompanied by intense neurasthenic symptoms, while a serious one may have few or none. This latter condition of affairs, however, is perhaps better designated as the exception rather than as the rule.

For the termination of my paper, I will briefly relate the histories of two cases, which I think will serve to illustrate my remarks.

Case I.—A gentleman, thirty years of age, presented himself somewhat less than a year ago, complaining that he was mentally harassed by sexual ideas and desires. He could not sleep peacefully, being frequently awakened by vivid erotic dreams, accompanied by strong priapism. When he would awake at such times he would always have a desire to masturbate, which sometimes was so pronounced as to be irresistible. In fact, occasionally when so awakened he would find himself in the act of masturbation. He had given up the society of ladies, as being in their presence even seemed to excite him. He found that the unsettled condition of his mind prevented him from applying himself to his profession. He was morbid, melancholy, and extremely irritable. His ideas of propriety were very elevated. He had never had sexual intercourse, and owing to his moral scruples declared he never could until married. He told me that in his present mental state he thought it wrong for him to think of associating socially with pure-minded women, while women of the other sort he could not endure. His mental distress, which was very keen, seemed centred in the idea that he was naturally impure minded; that he was, as it were, possessed of the devil. Before consulting me he had been advised that he had too much animal passion, and that in order to subdue it he should deny himself nutritious food—in fact, he should go to bed hungry, should sleep on a hard, uncomfortable mattress, and be provided with insufficient covering. As a result of this course of "pains and penalties," as it were, he had become worse, his animal passions being intensified rather than diminished. I asked him regarding his family history, and he pronounced it good. Afterward, however, I found that he had misunderstood me somewhat in this particular, thinking that my question referred to the mental status of his family. I also was somewhat at fault, perhaps, for not having cross-questioned him in this particular. I did, however, question him considerably, to see if I could find any evidence of perversion in his sexual instincts, but could not. His urine was absolutely normal, as was his function of micturition. On making a rectal digital exploration, I found a marked amount of chronic inflammatory thickening about both seminal vesicles, which rather surprised me in the absence of any venereal antecedent. I investigated the condition of the seminal vesicles very thoroughly, and as they were not so tender as usual I stripped them rather vigorously, in order to obtain some of the contents of the sacs. As these sacs lay in a mass of surrounding inflammatory exudate, some of which was organized, light digital pressure upon them would not have been productive of results in expressing anything along the ejaculatory ducts and into the urethra. The fluid so expressed was slightly purulent. As a result of my examination, I felt certain that all the symptoms complained of in this case were dependent on the seminal vesiculitis.

After several days the patient returned, stating that he had felt better in every way since my exploration. I accordingly stripped his sacs again, using moderate pressure, as they seemed rather more tender than when first examined.

In somewhat less than a week he came again—the third visit. He was greatly discouraged, stating that he was worse than ever. He was afraid he would lose his mind, or during a fit of despondency do himself bodily damage. On slipping my finger into his rectum, I found the seat of disease to be hot, throbbing, and congested, it being evident to me that my previous manipulations had been followed by an unduly severe inflammatory reaction, and this to my mind was the cause of his present distress. In my experience, no chronic seminal vesiculitis, unless it were tuberculous in character, presenting the evidences found in this case, would have been so affected by the treatment I had already given. Becoming suspicious that such was the probable nature of his seminal vesiculitis, I again questioned him regarding his family history. I then found that his mother had died while quite young, of some lung affection; that a sister had died of some wasting disease, she having previously suffered greatly from a painful swelling of a knee-joint, which caused her to be bedridden. A brother had been pronounced a consumptive, and had given up business for a life in the open air. As a consequence I immediately stopped all local treatment, and put him on a course appropriate for a tuberculous diathesis. Creosote, cod-liver oil, and moderate stimulation were prescribed, together with a rest in the country, combined with a liberal diet, the orders being to consume as much highly nutritious and easily digested food as possible. The patient gradually and steadily improved, and as his local inflammation became quiescent his nervous and mental symptoms disappeared. He is now happy and content. The inflammatory infiltration about his sacs has been absorbed, the organized cicatrix only remaining.

Case II.—A gentleman, about fifty years of age, first consulted me about nine months ago. For several years he had been much troubled by tingling, prickling sensations, extending down both thighs: by painful sensations shooting into the testicles, together with a feeling that those organs were heavy and required support. There were also at times a pain in the back and burning feelings in the rectum and urethra. He had been married about thirty years; had never had a venereal disease, and, in fact, declared that he had never had sexual intercourse with any woman save his wife. During the period his troublesome symptoms had persisted, he had spent most of his spare time and earnings consulting eminent medical authorities, the only result being that he was gradually getting worse and worse. His general physical condition was very satisfactory. He obeyed to the letter the rules of life which neurological authorities had prescribed. Not getting better under their directions, he had sought the advice of numerous surgeons. He had been to urinary specialists, who had washed his bladder, made all sorts of applications to his urethra, and finally cut and recut his urethra in the vain idea that perhaps a stricture existed. He had been to rectal specialists, who had performed several operations on his rectum. The operations on his urethra and rectum had done his symptoms no good, and had to a degree crippled those organs in the performance of their functions. On questioning him regarding his sexual function (and I was apparently the only one who had ever so questioned him), I found that at the present time he was weak and unsatisfactory in that particular, and that when he did perform the act ejaculation caused him pain, and for several days afterward his symptoms of complaint were worse. For several years he had attempted coitus very infrequently. During the first portion of his married life he was very amorous, and had indulged himself much, but never naturally, a systematic practice of withdrawal being observed, in order to protect his wife from conception—the sole legitimate object of marriage. On making an examination of the seminal vesicles, I found the cavities of both of them much distended, the walls of the organs being atonic, and also rigid and somewhat thickened, due to inflammatory infiltration. The prostate felt normal, and the loose connective tissue in the post-prostatic vesico-rectal space had been but little involved by inflammatory exudations. On stripping the sacs, the distention of which collapsed under the fin-

ger, a large amount of purulent material ran out of the ejaculatory ducts, a drachm or more of it dripping from the meatus. This material was swarming with infection, investigation showing the causative agent to be the colon bacillus. The portion of urine also passed immediately after the exertion of such pressure on the distended seminal vesicles was heavily charged with pus and bacteria, while the portion passed just before this manipulation was in great measure free from these pathological elements.

As a result of treatment directed solely toward the seminal vesicles, these sacs being methodically emptied according to my method by means of the finger introduced into the rectum, the element of infection has been in great measure eliminated, while the sacs are gradually losing their inflammatory thickening and regaining their muscular tone. Owing to this local improvement the patient has already been freed from many of his neurasthenic symptoms, while those that remain are greatly modified as regards intensity. The symptoms which persist will wholly disappear with further resolution in the seminal vesicles. In a case such as this, owing to the age of the patient and the chronicity of the lesion, it is probable that several months' more treatment will be necessary before the end result is obtained.

THE ASCH OPERATION FOR DEVIATIONS OF THE CARTILAGINOUS NASAL SEPTUM, WITH A REPORT OF TWO HUNDRED OPERATIONS.[1]

By EMIL MAYER, M.D.,

SURGEON OF THE NEW YORK EYE AND EAR INFIRMARY (THROAT DEPARTMENT); FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, NEW YORK ACADEMY OF MEDICINE; MEMBER OF THE COUNTY MEDICAL, HARLEM, AND GERMAN MEDICAL SOCIETIES.

Deviations of the cartilaginous septum may be of recent origin, or they may have existed for a long time. If of the former class, they are invariably due to some form of violence, while in the latter they may have other causes due to some faulty development, being practically congenital in their origin.

When they are of recent origin, the surgeon is most apt to be consulted. If of long standing, they are generally discovered by rhinologists in their search for the cause of the train of symptoms complained of and which they occasion. These symptoms are mainly permanent obstruction to respiration on one side, mouth breathing, dryness of or excessive secretion in the throat, constant rasping, fitful sleep, nasal voice, epistaxis, aural diseases, diminished hearing, persistent headaches, and many reflex disturbances. It frequently happens that the patient is not aware of the nature of the diseased state which causes his complaints.

Deviation of the cartilaginous septum may be defined to be a deflection from the normal straight line to one side, filling the nasal cavity more or less completely, accompanied by a corresponding depression on the side opposite. For simplicity of description the deflected or obstructed side is called the convexity, the other the concavity. It offers no difficulties in the way of diagnosis, and can be ascertained to exist by either or all of the following methods: Obstructing the nostril on the concave side and requesting the patient to blow, either no air or a very thin stream is felt upon the hand. Reversing the procedure, a full free current is obtained. By dilating the nostril with a speculum, or even raising it with the finger, the deviated portion is readily seen, the convex side filling the nasal space. Touching with a probe reveals its firmness. Cocainizing produces no retraction, and usually the probe, having passed beyond the obstruction, readily enters the nasopharynx.

Deviations may be differentiated from tumors and exostoses by the presence of the concavity on the opposite side, as also by the touch.

It would prolong this paper unnecessarily to mention all the various methods that have been proposed to remedy this condition. Suffice it to say that most of them have a technique of so intricate a nature that the ordinary human mind despairs of following their bewildering details. Others again are simple enough, but are only rarely employed, because the results do not justify their continuance.

The importance of protecting the nasal mucous membrane, and not destroying it, is now so fully recognized that the galvano-cautery may not be employed, and for the same reason the saw must be condemned. Many have discarded the use of the saw altogether, but, as I find it still mentioned in text-books, I may say that the manner of procedure is to cut through the convexity "deep enough, but not too deep," from below upward, until the membrane opposite is reached, when with the cold wire snare the dangling piece is removed.

The objections to this method are destruction of a large surface of normal mucous membrane, possible perforations or adhesions, and practically a continuance of the diseased state. The cartilage of the septum is very resilient, and only that operation can be successful that leaves the mucous membrane intact, results in a straight septum, destroys its resiliency, and is lasting in its results. All this has been invariably achieved by the operation I now describe.

This operation was first performed by Dr. Morris J. Asch, of this city, in 1882, and a report of it was made at the twelfth annual session of the American Laryngological Association, at Baltimore, in 1890. In this paper but six cases were reported. In a subsequent paper on this subject by myself twenty successful operations by this method were presented. It would seem that the number of cases heretofore reported is not sufficient to secure the unqualified indorsement of the profession. This becomes apparent if we note that a careful research in many of the text-books devoted to rhinology and its allied branches fails to disclose any mention of this operation, and that Dr. Victor Lange, of Copenhagen, who is the author of the article on deviations of the cartilaginous septum in Heymann's "Handbook of Laryngology and Rhinology" (Vienna, 1897), after describing many of the operative measures devised for the cure of this condition, concludes thus: "We are assuredly unable to judge of the merits of any operative procedure as long as it is based on a few cases. No method can be fully accepted, nor ought it to be, until a reputable number of cases, carefully noted and criticised, shall have been presented."

The two hundred cases, all successful, embodied in this report will, I trust, be considered sufficient to enable an unprejudiced observer to judge of the merits of this operation.

To avoid any possibility of question, no mention is made here of any cases performed in private practice by any operator. Those taken from the report of Dr. James F. Grant, house physician at the Manhattan Eye and Ear Infirmary, and compiled by him from the public records of that institution, are seventy-eight in number, and were operated upon by various surgeons during the past eight years.

The one hundred and twenty-two remaining cases were operated upon at the New York Eye and Ear Infirmary, from 1888 to November, 1897, and are tabulated from the records of that institution by Dr. Frank G. Ketcham, house surgeon.

A summary of these shows that there were ninety-six

[1] Read before the section on surgery, New York Academy of Medicine, January 10, 1898. (The tabular list of operations is omitted here for want of space, the author having given his summary of them in the body of the paper.)

males and twenty-six females operated upon; the youngest being five years old and the oldest sixty-seven years old, the average age being twenty years. The operation was performed thirty-nine times by Dr. Asch; thirty-five times by Dr. Mayer; eighteen times by Dr. Hitchcock; sixteen times by Dr. Adams; three times

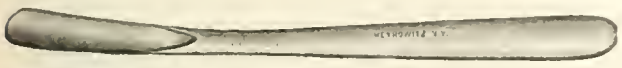

Fig. 1.—Gouge.

by Dr. Waterman; three times by Dr. Simpson; twice each by Drs. McKernon and Gage; once each by Drs. Whiting, Leonard, Concannon, and Bardes. One was operated upon under cocaine anæsthesia, the others under ether. Of the seventy-four cases operated upon by Dr. Asch and myself, the after-treatment was under my immediate supervision, always enabling me to note their progress. These cases are all marked "cured" in the column of results. That is to say, in each and every instance the stenosis was permanently relieved. In eighty-five per cent. a perfectly straight septum was the result, while in the remainder the septum retained some degree of curvature, but never sufficient to cause any stenosis or discomfort whatever. This I was able to demonstrate by presenting cases to the laryngological section of the New York Academy of Medicine, operated upon five, six, seven, and eight years before.

Perforations occur in about two per cent. of the operated cases, are usually about the size of a pin's

Fig. 2.—Elevator.

head, and are caused by the curling up and sloughing of the edge of one of the segments. In no single case was there any alarming hemorrhage, either at the time of operation or subsequently. No septic conditions resulted, no disagreeable after-effects; no disturbance traceable to the operation occurred, nor was there at any time any danger to life. These results are the more remarkable in that these operations were performed upon dispensary patients, whose physical conditions are rarely of the best.

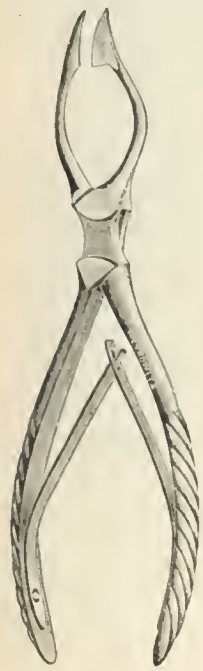

Fig. 3.—Straight Scissors.

The instruments devised by Dr. Asch are here presented. There are two separators (Figs. 1 and 2), one with a blunt edge and the other sharp, to break up any adhesions existing between the septum and the turbinate on the affected side, as also to destroy any posterior obstructions. The scissors (Fig. 3) are of two sizes. These are powerful instruments, curving outward from the point of crossing and meeting again in front. One blade is blunt, while the other is sharp with a triangular blade, the apex of which is at the tip. The other scissors (Fig. 4) are made with the blades bent at right angles, and are occasionally necessary for those deviations that lie low down on the floor of the nose.

There are two compressing forceps (Fig. 5), one having a long and the other a short beak.

Hollow tubes of vulcanite are made (Figs. 6 and 7) with a slight curve on the under surface, in accordance with the normal curve at the entrance of the vestibule of the nose. These tubes have perforations to prevent their slipping out when inserted. They are of differ-

Fig. 4.—Angular Scissors.

Fig. 5.—Compressing Forceps.

ent sizes and shapes. Those known as the Asch tubes are of five sizes, somewhat oval in shape, and those known as the Mayer tubes are of six sizes, more oval and considerably flatter on the sides. These vulcanite tubes are so prepared that they retain their shape when subjected to the heat of a sterilizer.

The operation is best performed under complete anæsthesia. Cocaine does not appear to be of value here, it being necessary that the patient be recumbent, and in the efforts to dislodge the blood flowing into the pharynx the operator is seriously interfered with. The nose is sprayed out immediately preceding the operation, for which purpose an alkaline antiseptic, like the Dobell solution, is used. The usual preparations for anæsthesia are made, ether or chloroform being the anæsthetic used. All instruments are carefully sterilized. The use of an antiseptic spray and the sterilization of instruments for an operation when the air cannot be excluded either before or after operation may be explained by stating that we know that by such care we are surely not adding any infection by our operative procedure. Complete anæsthesia is required. The cone being removed, it never becomes necessary to have recourse to it again, as the operation

Fig. 6.—Asch's Hollow Splint.

Fig. 7.—Mayer's Hollow Splint.

is rapidly performed and completed before consciousness is regained.

The head is well drawn backward, in order that blood may not enter the larynx, the table being so placed that either the direct or artificial light may be used.

The blunt separator is now introduced sideways on the deviated side, in order that any adhesions existing between the septum and its adjacent mucous membrane may be broken up, enabling us at the same time to ascertain the presence of bony obstructions posteriorly. Should these latter exist or the adhesions be non-yielding, the separator with sharp edges is re-

quired: this, however, is rarely necessary. There may be some hemorrhage after the adhesions are broken up, but it is readily checked by an iced spray, or by pressure of cotton applicators. The open scissors are now introduced parallel to the floor of the nose, the blade in the concavity, the blunt edge over the point of greatest convexity. They are then firmly closed, the blade cutting through the cartilage into the opposite side with a distinct snap. The scissors are then opened and completely withdrawn. They are immediately reintroduced, the direction of the instrument being upward this time, pointing to the frontal bone, the blade again in the cavity and crossing the line of the first incision at as nearly a right angle as possible, and at its centre. In this way the incisions will intersect each other: the scissors are now firmly closed and the second incision is made, after which the scissors are opened and withdrawn.

We now have four segments as a result of this crucial incision. The finger is then introduced in the deviated side and the segments are forcibly pushed into the concavity, effectually breaking them at their base.

The powerful blunt forceps is now introduced, one blade in each nostril, and firmly closed, thus straightening the septum and forcing the broken segments to override each other in the concavity. The compression aids also in controlling hemorrhage, and the parts are firmly held in apposition. An iced antiseptic solution is sprayed in both nostrils, the forceps being withdrawn. The sterilized tubes are then introduced in the nose, a snugly fitting one on the stenosed side and a smaller one in the opposite nostril, thus causing equable pressure, their presence being usually all-sufficient to control hemorrhage. The operation is now completed. The amount of blood lost varies with each individual, but is invariably promptly checked when the pressure is applied.

The patient is placed in bed, cold antiseptic sprays are used half-hourly, and iced cloths are applied externally.

Twenty-four hours after operation the tube in the former concave side is withdrawn and not replaced. The antiseptic spray is used once every hour or two and the compresses are continued. Twenty-four hours later the tube on the stenosed side is removed and thoroughly cleansed. The nose is freely sprayed and cleansed with cotton probes, cocaine being used if sensitive. The same tube is reinserted, unless too large for comfort, when a smaller one is used, the rule being to use a tube large enough to be introduced without force, and yet to fill the cavity, no part of it protruding from the nostril. On this day patients are permitted to arise from the bed and assume other than a recumbent posture, the compresses being discontinued. On the third day the tube is again removed, cleansed, and reinserted, and the patient allowed to go home. For the next three or four days the patient presents himself daily for the removal, cleansing, and reinserting of the tube. At each time of removal the nose is thoroughly cleansed and freed from secretion and clots. Within this first week the patient has learned to extract and reintroduce the tube himself, in the presence of the surgeon, and hereafter performs it once or twice daily at home. The directions are given to remove the tube, spray out the nose, or insufflate warm salt water to which an alkaline antiseptic is added, and then to reintroduce the cleansed tube. The extraction and reinsertion of the tube are quite painless after the first week, and it is remarkable how easily the youngest patient becomes accustomed to it. The patient is now seen once or twice a week for the next four weeks, at the end of which time, five weeks from the day of operation, the tube is finally withdrawn for all time.

The mass of bent cartilage has disappeared, the septum has become straightened and remains so, and very often the external deformity no longer exists.

Sometimes during the five weeks that the tube is in use it may appear that the septum is bulging greatly on the stenosed side, but it is well to leave it quite alone, as the constant pressure reduces it finally, for there seems to be a resorptive process going on.

It occasionally happens that the lower segment remains thickened after the five weeks have elapsed, and presents the appearance of a spur or enchondrosis. This is treated as such and removed by the electrotrephine or galvano-cautery. The latter has worked splendidly in my hands, especially in nervous individuals and children. The parts are cocainized and then cauterized with a platinum knife. There is no bleeding and the patient is not aware of any operative procedure. A light packing of iodoform or sublimate gauze is introduced daily for the next few days after cauterization.

During the five weeks that the tube is in place, excepting the first three days, the patient resumes his usual vocation, children go to school, and adults find no interference in their work.

The segments which were pushed into the concavity, thus destroying the resiliency of the cartilage, overlap each other, become firmly adherent, and in a short time there is no evidence of any unusual condition whatever.

The advantages of the tubes can hardly be overestimated, establishing comfort at once by allowing air to pass through, and acting as splints to keep the septum straight; the readiness with which they are removed and reinserted making them infinitely superior to the original method employed of packing with absorbent cotton about a tin splint.

When deflections are very recent a modification of this operation may be advisable, as I have successfully tried it in a case referred to me by Dr. C. E. Clark.

Mr. H——, aged twenty years, clerk, presented himself on July 18, 1895, with the following history: On July 1, 1895, while riding a bicycle at full speed and meeting an obstruction, he was thrown forward, falling on his face. His nose was much swollen and had bled profusely. After most of the swelling had subsided his nose was flattened and painful, and stenosis was almost complete.

An examination showed fracture of the left nasal bone, with depression and a deviation of the septum to the right. The deformity was very great. With the nasal forceps I compressed the septum, straightening it and raising the depressed nasal bone. I then inserted a conical nasal tube, on the withdrawal of the forceps. This tube was perforated and of vulcanite, and was shaped like a truncated cone. The tube came out the next day and was again replaced, after straightening. It then remained *in situ* for three days, when I removed it, cleansed it, and reinserted it.

After the first day there was no pain or discomfort in wearing the tube, and the patient breathed freely through both sides. The tube was now left *in situ* for a week and then removed, cleansed, and reinserted. After this the patient removed the tube daily.

On August 26th, after he had worn the tube for five weeks, it was discarded altogether. He has now no difficulty in breathing and there is little deformity.

Re-examined, October 21st: Septum nearly straight, free current of air established. Some bony irregularity felt on the left nasal bone, where the fracture was. There is an entire absence of deformity.

It is now fifteen years since the Asch operation was first performed, during which time I have had ample opportunities to note every possible form of deviation and complication. A retrospect of the many cases

attended, all of them permanently benefited by this operation, places me in the position of having unbounded confidence in this procedure, and enables me to state as a result of my experience that this is the best operation yet devised for the cure of deviations of the cartilaginous septum, because of its simplicity, the immediate benefit following it, and the permanent nature of the results thereby attained.

List of Asch operations for deviations of the cartilaginous nasal septum performed at the Manhattan Eye and Ear Hospital and the New York Eye and Ear Infirmary, from 1888 to 1897.

REPORT OF A CASE OF NEPHRECTOMY FOR STRICTURE OF THE RIGHT URETER AND EARLY TUBERCULOSIS OF THE KIDNEY.[1]

By HIRAM N. VINEBERG, M.D.,

NEW YORK.

Mrs. S. L—— was referred to me by my friend, Dr. M. Manges, on June 15, 1897. She was forty-eight years of age, married twenty-one years, and had had five children. The menopause had become established four years before. Six months ago she began to suffer from attacks of pain in the right loin and back. These attacks were attended by nausea and vomiting. Three months later she came under the treatment of Dr. Manges, who examined the urine and found a small quantity of pus in it. He prescribed methylene blue, which at first afforded very great relief, but for the past few weeks the remedy had lost its efficacy and the symptoms now had changed their character. The pain was situated more in the hypogastric and right iliac regions, and the frequent micturition which had been a symptom from the outset now became more severe. The pain, however, at times would extend to the right lumbar region.

The patient was of medium build and rather old in appearance for her age. The right kidney could not be distinctly palpated. It certainly was not found enlarged. On bimanual examination a cord-like structure, about the size of a lead pencil, was palpated in the anterior vaginal fornix, running upward to the right. This was taken to be the right ureter, which had undergone thickening. A cystoscopic examination after Kelly's method, with the patient in the knee-chest position, disclosed the orifice of the left ureter apparently normal, emitting jets of clear urine from time to time; and adjacent to it were a small patch of redness and a bleeding spot the size of a pin's head. The orifice of the right ureter was irregular in outline, swollen, and presented a nipple-like projection. Urine was seen oozing from it, continuously rather than in jets. Scattered over the whole trigone of the bladder were small red areas, such as one usually sees in localized cystitis in women. At a subsequent examination a catheter was readily passed into the left ureter and clear urine withdrawn. On attempting to pass a catheter into the right ureter, it was found to meet with an obstruction about one inch from the bladder. One of Kelly's ureteral sounds of small calibre was obtained, and this also was arrested at about the same distance in the ureter.

A diagnosis of stricture of the right ureter with localized cystitis was made. Under the direct application of a five-per-cent. solution of nitrate of silver, the red patches disappeared and the bladder symptoms—such as frequent micturition and pain over the hypogastrium—were completely relieved.

The urine was frequently examined during this time. No abnormal elements were found, excepting a few red blood cells and leucocytes. Dr. Heiman kindly examined the urine a few times for tubercle bacilli, and always with negative results.

The patient's general condition improved, and she gained considerably in weight. For a time it seemed as if she were going to make a complete recovery; but on the night of August 19th she had a severe attack of pain in the right iliac region, extending backward and upward to the back. Toward the end of the attack she passed urine containing considerable blood. This was the first time to her knowledge that she had passed any blood with her urine. The specimen of bloody urine was sent to Dr. Heiman, who reported he could find no kidney structures, no tubercle bacilli, nor any oxalate-of-lime crystals indicating a calculus. He gave it as his opinion that the blood came from the lower urinary tract and certainly not from the kidney.

August 20th, at 2 P.M., I made another cystoscopic examination. The urine now withdrawn was of a clear amber color and entirely free from blood. The bladder surface appeared perfectly normal. The right ureteral meatus, as before, was seen to be irregular, reddish, and swollen. The left ureteral opening was normal in appearance.

The patient was one of those highly intelligent and superior women in whom one unconsciously takes a great interest, which in this particular instance was heightened by the fact that the welfare of a growing-up family depended solely upon her. I was therefore doubly loath to subject her to a radical operation before exhausting all other means. Consequently, after securing Dr. Manges' approval, I advised her to go to Baltimore to consult Dr. Howard Kelly, in the hope that he might be able to suggest some plan of treatment which would obviate a major operation. His letter to me, after seeing the patient, is so interesting and instructive that I may be pardoned for transcribing it in full.

"Baltimore, October 4, 1897.

"Dear Dr. Vineberg: I was glad to see so interesting a case as that of Mrs. L——. I thank you for your courtesy in the matter. I found her well prepared for examination, and was able to do all that could be done in a twenty-four hours' visit.

"I found a healthy bladder and an apparently sound left ureteral orifice issuing jets of clear urine. The right ureteral orifice was flattened, mammillated, slightly dull, white in the trigonal, and injected on the outer side. Urine escapes on the right but not regularly, as on the left side. Testing with a ureteral catheter, both elastic and metal, I find she has a marked stricture of the lower end of the right ureter.

"On attempting to pass a wax-tip bougie (one part oil, two parts wax), the hard wax tip was wiped clean of its wax by the tight, rigid stricture. Separated urine from this side could not be secured. It is probable from this that all abnormal elements came from this side; but this can be assured by emptying the bladder and passing a 2 or 2½ mm. catheter into the left side and isolating left urine, and leaving a soft

[1] Presented at a meeting of the obstetric section of the Academy of Medicine, October 24, 1897, and at a meeting of the Metropolitan Medical Society, October 23, 1897.

rubber catheter in the bladder, at the same time draining off urine escaping from the right ureter into the bladder.

"The diagnosis, I think, rests between calculous pyelitis and stricture of the ureter due to traumatism or ulceration. I think the symptoms are abundant to warrant your making incision, exposing and opening the kidney, and thoroughly exploring for calculus. I would then pass a catheter, say No. 2¼ or No. 2½, down the ureter as near as possible to the bladder; by locating the end of the catheter by the rectum or by the vagina, you will be able to discover the upper limit of the stricture, and to determine whether it would be possible to overcome it by slitting up the ureteral orifice in the bladder or by turning the ureter into the bladder at a point a little higher up. If you found a stone, you would of course be encouraged to keep the kidney; but if the pain comes from the backing up of the urine behind the stricture, and the stricture is of such length that the prospects of relieving it are but slight, I would not then hesitate to sacrifice the kidney in order to give entire relief to the symptoms.

"I shall feel deeply interested in hearing from you as to your further treatment in such an interesting case. Very sincerely yours,

"Howard A. Kelly."

Both Dr. Manges and myself favored the diagnosis of a tuberculous lesion, inasmuch as the patient's family history manifested a tendency in that direction—a brother having died of Addison's disease.

On October 11th I carried out Dr. Howard Kelly's suggestion to isolate the urine from each kidney in the manner described in his letter. I left the catheter *in situ* in the left ureter for about one-half hour, and the procedure was progressing satisfactorily — the urine from the left kidney being quite clear; that from the bladder, and hence from the right kidney, slightly turbid; but just as I was about to withdraw the ureteral catheter, some blood appeared from the catheter and some escaped also in the bladder.[1] This unfortunately is not an uncommon occurrence in catheterization of the ureters, and is due to traumatism. Casper states that it occurs in fifty per cent. of his cases. In my patient there was no further discomfort from the examination than some pain in the left side for the next twenty-four hours. The microscopic examination of the two urines was negative, excepting for the presence of the numerous blood corpuscles.

On October 22d I operated upon the patient at St. Mark's Hospital. After exposing the kidney and finding it rather extensively adherent to the perirenal fat, and being unable to detect any stone in it, I decided to extirpate it without any further experimentation in the direction of the ureter. The extirpation was done in the usual manner and the wound sutured in layers, a gauze drain being left at the upper angle.

The patient made a good recovery, and left the hospital before the end of the fourth week. The urine is now voided normally, without any pain, is quite clear in color, and is free from any abnormal elements.

The removed kidney presents the following characters: It is rather long and narrow, giving the following measurements: length, 11 cm.; circumference at the lower, larger pole, 13 cm.; circumference at the upper pole, 10.5 cm. The capsule is of a dark bluish color. On longitudinal section two small abscesses are disclosed: the one, about the size of a small kidney bean, is situated in the cortical substance immediately beneath the capsule, at the junction of the middle with the upper third; the other, about the size of a split pea, is situated just internal to the first, and seems to involve one of the pyramids. Its walls are corrugated, looking not unlike a "corpus luteum." A short distance above the abscesses, immediately beneath the capsule, is a group of about twelve miliary tubercles. The pus obtained from the abscesses contained tubercle bacilli.

It was fortunate for the patient that in addition to her tuberculous kidney she had a stricture of the ureter; for in its absence I question very much whether we would have felt justified in resorting to a major operation for the indefinite clinical phenomena present.

The discouraging features generally attending operations for tuberculosis of the kidney arise from the circumstance that they are not undertaken as a rule until the disease is far advanced and probably transmitted to the opposite kidney. But with more general cystoscopic examinations there is hope that in the future early tuberculosis of the kidney will be more frequently recognized. One of the valuable signs of such a condition is marked changes in the orifice of the corresponding ureter. Hurry Fenwick and Willy Meyer have each reported a case of early tuberculosis of the kidney in which this was the only prominent sign present. Willy Meyer goes so far as to say that, if he found marked redness of one ureteral orifice without any changes in the bladder elsewhere, he would diagnosticate tuberculosis of the corresponding kidney. After rather an extensive experience with the results of cystoscopic examinations in women during the past three years, I would not be willing to subscribe to so radical a statement. In women (my experience extends only to the female sex) it is not infrequent to find a small red area, which may be situated about one of the ureteral orifices, and which readily disappears with appropriate treatment, as do also the urinary symptoms present. I recall one case in particular, of a woman who had suffered for months with frequent micturition and pain in the left iliac region, extending to the left lumbar region. Cystoscopic examination revealed a moderate-sized red patch immediately surrounding the left ureteral orifice, the lips of which were considerably swollen. The red patch totally disappeared after a few direct applications of a solution of nitrate of silver, and the patient was relieved of her symptoms and has remained well now a period of several months.

In the foregoing case, besides those already emphasized, there are three points of particular interest to which attention was drawn by Dr. M. Manges, when the case was presented at a recent meeting of the Metropolitan Medical Society: (1) The marked improvement in the symptoms at first afforded by the administration of methylene blue. (2) The decided increase in weight of the patient and improvement in her general condition for the three months prior to the operation, though the local tuberculous affection must have been extending. (3) The absence of tubercle bacilli in the urine, in spite of the repeated examinations by Dr. Heiman and himself.

The centrifugal process was made use of in the examinations.

127 East Sixty-First Street.

[1] It may be of interest to add that all of the examinations were made without general anæsthesia and that they were attended by little or no suffering.

Contusions.—Dr. Namé (*Journal de Médecine*, September 12th) gives these directions for the treatment of contusions: 1. Rigorous antisepsis, careful cleansing of the parts with ether. 2. The application once or twice daily of collodion, containing from ten to twenty-five per cent. of menthol. Under this treatment the pain quickly subsides, and the constrictive influence of the collodion causes the disappearance of the effusion in from two to five days. Extensive contusions about the joints are not so favorably influenced.

NOTES OF A MEDICAL MISSIONARY.

By J. HUNTER WELLS, M.D.,
PYENGYANG, KOREA.

It is not easy to select from over ten thousand patients, seen within eighteen months, those diseases or cases which might prove interesting or instructive, though it does seem that a competent observer might draw some deductions from that mass of misery which would be helpful to somebody in similar or even in different circumstances. The general run, however, being but little different from the crowds that annually pass through the departments of the larger New York or European hospitals, the only advantage or disadvantage one has out here on the edge of the Orient is that every patient must pass through his hands, compelling one to turn from specialist to general practitioner from minute to minute. This makes the work of a medical missionary, of which I am a humble representative, varied and interesting, and ought to enable him with such splendid chances to add something to the credit of our craft—although, alas! how rare it is that we see anything from the pens of these very general general practitioners.

A well-known writer has said that if he were Tsar of the world he would make a law that no one should write of a country or a people until he had dwelt two years among them. Acting on this principle, I made a rule that I would not report any plan of treatment or series of experiments until I had at least one hundred cases to illustrate with. And so, up to this time, my only report has been on the Asiatic cholera, a statement of which appeared in the MEDICAL RECORD, vol. 48, p. 495. I have since had many more than one hundred cases of tuberculosis which I treated with permanganate of potassium with negative results, and, so following, hundreds of other cases of other diseases; but the difficulty of keeping them in sight has prevented any good tabulation. I have had one satisfactory result with the above drug in tuberculous ulceration, one-fourth grain internally three times a day, but am not convinced that an equally good result would not have followed bread pills.

There is one disease here, the native fever, which I have not been able to study bacteriologically as yet, but which clinically yields readily to quinine, phenacetin, cold baths, and stimulants. We use the drugs and baths to reduce the temperature, and then use the stimulants to get it up again, deriving our authority from that classical case of the man who jumped into a bramble bush. The onset of the disease is sudden and the course of the fever does not usually last longer than a week or ten days. A temperature of 106° F. is common. The general rule among these people is quick recoveries. Affections that would confine Anglo-Saxons for two weeks are thrown off here in half the time. Whether no restrictions as to food in fevers, and a little more trusting to nature than is usual, have anything to do with it or not, is an open question. In childbirth the women are up and working a day or two after confinement. The gynæcologist not having arrived, there is no apparent need of him; but then corsets, high-heeled shoes, late hours, and such products of Western civilization have not made their influence felt in the shining Orient yet. There are no Pasteur institutes, and so hydrophobia is rare—though we notice the same fear and dread of a "mad dog" that we know of in the West. I lately saw a crowd chase, capture, and kill what they called a mad hog—which was just an ordinary, plain, frightened pig. No care is taken of the insane, and there is no apparent need of any, for during my residence here and in other parts of the country for two years I have not seen more than twenty such people altogether.

Quinine, as I suppose is the case everywhere on earth, is by far the most commonly used drug. The natives buy it by the thousands of bottles yearly, and dispense it themselves.

Santonin for worms comes next, for the diet of rice and weeds makes this trouble a constant one. The habit the natives have of shovelling the food into their mouths produces "indigestion" as a national ill. A mixture of quinine, nux vomica, and capsicum is the best remedy for that.

Tuberculosis in its various forms holds its terrible head as high as in other countries, and slays its thousands just as uninterruptedly. Scrofula and syphilis, with skin diseases rare and common, are met with in expected proportion, and so down through the list.

Minor surgery, and just over the border into the other kind, are what constitutes our most spectacular work, though that on eyes is the happiest in its results. Cataracts are fairly common, and the cicatrices from corneal ulcers obscuring the sight are easily relieved by extraction and iridectomy. I have had over fifty such cases within the past six months.

The experience of running a missionary hospital might be of some interest. The building, a small affair, cost some $1,200. It accommodates between thirty and fifty in-patients. The floors in the wards are of stone covered with clay and paper, and are heated underneath. The patient's board, three meals a day in the style and quantity which prove fattening, costs twelve cents a day. My first assistant, who is druggist and "doctor," receives $3.50 a month; to a second one is paid $3; and to a boy for errands, etc., $1.80. Drugs and supplies, including surgical instruments and appliances, are obtained in Japan for less than half what the same German imported drugs cost in America; so that for eighteen months the entire expense, including everything but my salary, amounted to only $1,000, of which $700 came from America and $300 from the natives here. Hospitalism at a cost of ten cents a patient!

The many phases of our work, and the many other duties expected of us besides professional, and the inability to follow up all our cases, prevent proper scientific work. There is no reason, though, why the hundreds of doctors at work all over the world with such splendid clinical advantages should not contribute something of value very often to our profession. One general principle, well proven without more words, is that we need not expect good surgical results without surgical cleanliness, and this is much more easily secured than we think. I find that I can do with cocaine many operations that I was taught required a general anæsthetic. The radical cure for fistula in ano is done without any anæsthetic, and an almost daily scene in my clinic is to turn from eye surgery to rectal surgery, and then to some other specialty.

Morbid Conditions Found in the Appendix may be grouped under the following six heads: (1) The appendix is surrounded by dense inflammatory adhesions inclosing an encapsulated abscess; (2) an enterolith is imprisoned in the appendix, with occasional distention of its blind end with pus; (3) the lumen of the appendix is destroyed by ulceration, and its distal end is distended with mucus or pus; (4) the appendix is free but much thickened, resembling a mass of cartilage rather than a mucous tube (such an appendix is occasionally lengthened and unequally distended along its length); (5) the appendix is coiled upon itself, or acutely "kinked," and fixed in this position by adhesions; and (6) the appendix is surrounded by dense old adhesions, matting it to the cæcum, small intestines, bladder, rectum, or the abdominal wall.—DR. GEORGE HEATH, *Lancet*, May, 1897.

REACTION TIME IN ABNORMAL CONDITIONS OF THE NERVOUS SYSTEM.

By E. W. SCRIPTURE, Ph.D.,
NEW HAVEN, CONN.,
DIRECTOR OF THE YALE PSYCHOLOGICAL LABORATORY.

Among the investigations that have recently been brought to completion in the Yale Psychological Laboratory, there is one that may be of interest to the medical public; I will summarize the results from the more extended account which will appear in No. 4 of my "Studies."

The research on reaction time in abnormal conditions of the nervous system was conducted by Dr. A. G. Nadler at the University Clinic. In one set of experiments the subject was required to press a key as soon as a colored disc was exposed; the time required for this process, "the simple reaction time," was measured by a chronoscope in thousandths of a second. In another set the subject was required to react when a red disc was seen, but to refrain when a white disc was seen: this was the "complex reaction time," involving the processes of discrimination and choice in addition to simple reaction.

Four types of disease were investigated—neuritis, locomotor ataxia, alcoholism, and hysteria. The results are summarized in the following table; records from nineteen college students are added under "Normal," for the sake of comparison. All records were made with the Scripture pendulum chronoscope.

As a concrete example we may suppose the following set of seven reaction times to have been obtained. The results are placed in column r. The average is calculated as usual; then the difference is found between each record and the average, and is placed in column u. The average for column u gives an index to the subject's irregularity.

r	u
174	24.7
124	25.3
156	6.7
130	19.3
166	16.7
141	8.3
154	4.7
7)1045	7)105.8
149.3	15.0

This irregularity is an important characteristic of the subject. The average of the reaction times r for the whole group is given as R in the following table; the average of all irregularities u is given as U. In a similar manner we can take the result for all the individuals of a group, and can calculate the average divergence of the members of the group from the final average. These results, given in columns V V', indicate how closely the members of a group agree together; close agreement means that—in this particular property—the group is a well-defined one. The results for complex reaction time are similarly computed.

Disease.	R	U	V	C	U'	V'	B	k
Local neuritis	360	42	67	570	63	135	210	11
Multiple neuritis	418	35	4	848	63	54	430	3
Locomotor ataxia	387	8	7	786	23	42	399	4
Alcoholism	163	13	7	440	26	48	277	17
Hysteria	192	53	51	671	100	96	479	12
Normal	179	29	31	349	58	58	170	19

R, simple reaction time.
C, complex reaction time.
U, U', averages of the individual mean variations.
V, V', average departures of the individuals from the typical averages R and C.
B, difference between C and R, or time for discrimination and choice.
k, number of individuals; forty records on each individual.

The following conclusions seem to be justified by the table:

1. Alcoholism shortens the simple reaction time; hysteria leaves it unchanged; and local neuritis, multiple neuritis, and locomotor ataxia lengthen it (column R).

2. Local neuritis scarcely lengthens the additional mental processes involved in complex reaction time; alcoholism lengthens them somewhat; while locomotor ataxia, multiple neuritis, and hysteria double and triple the normal time (column B).

3. The individual's regularity is much greater than the normal in locomotor ataxia and alcoholism, and much less than the normal in the other diseases. The irregularity is specially marked in hysteria for the higher mental processes (columns U, U').

4. Subjects with multiple neuritis, locomotor ataxia, and alcoholism are much more distinctly marked off in respect to these tests than normal individuals. The close agreement of the seventeen alcoholic patients in regard to simple reaction time is very remarkable (columns V, V').

Summing up by diseases, I believe it justifiable to say that in the two respects of simple and complex reaction time they are characterized as follows:

1. Local neuritis: A poorly defined group with long simple reaction time and great irregularity.

2. Multiple neuritis: A very closely defined group with very long time for both simple reactions and more complicated mental processes; also considerable irregularity in the individual.

3. Locomotor ataxia: A very closely defined group, slow in reaction and in the higher processes, but astonishingly free from individual irregularities.

4. Alcoholism: A very closely defined group, with accelerated reaction time and not greatly retarded complex time, remarkably free from irregularity.

5. Hysteria: An indefinite group, with normal simple reaction time but greatly lengthened complex time, exhibiting extreme irregularity.

Progress of Medical Science.

Comparative Pathology illustrates in all animals these main truths: that a healthy complex life is constantly at war with lower forms of life, and in direct proportion to its complexity has it always acquired a greater resisting power to the attacks of lower forms. Thus, as we descend in the scale of animal life from man downward, we always find the resisting power to disease less, the duration of the fight against sickness less, and the pathological processes much quicker. This is true of inflammatory action, formation of tumors, course of fevers, and even of the ordinary processes of nutrition.—Dr. Charles Gresswell, *Colorado Medical Journal*, December, 1897.

Therapeutical Application of Curdled Milk.—In 1888, Dr. Paschayan (*La Médecine Moderne*, August 25, 1897) was physician for the municipality of Palou, where he had occasion to observe the therapeutical effects of curdled milk in diseases of the digestive tract and in febrile affections. He noticed that the natives obtained good results with curdled milk in acute enteritis; the patients were often cured in three or four days without the employment of any other medication. It was likewise employed in typhoid fever as a cooling drink. Since that time the author has recommended curdled milk to patients affected with acute enteritis, dysentery, and acute and chronic gastritis. He has also administered it as a cooling drink in typhoid fever. The patients find it agreeable and easily digested; the diarrhœa ceases, the dyspepsia becomes less, and the general condition is improved.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 5, 1898.

THE INTERNATIONAL-LANGUAGE QUESTION.

We have received from Secretary-General Amalio Gimeno the announcement and preliminary programme of the Ninth International Congress of Hygiene and Demography, to be held in Madrid in April of the present year, and our attention is called to the formidable list of official languages, which number no less than seven. Any member is privileged to address the congress in Latin, Spanish, Portuguese, Italian, French, German, or English, or in all together if he is able and so desires. Whatever speech he selects, he will have the certainty that about one-fourth or possibly one-half of his fellow-members will have a faint and confused idea of the subject of his address, while the rest of his auditors will be bored beyond expression by the flow of his (in their ears) uncouth eloquence. With each recurring international assemblage of whatever character, this question of a common medium of communication presents itself with ever-increasing urgency. The Moscow meeting of last August was no exception to the rule in this respect. Indeed, the difficulty of an interchange of thought was there even more than usually accentuated, by reason of the interjection of the Slavonic tongues into the Babel of official languages. Men who possessed a serviceable familiarity with the three official tongues found themselves entirely shut out when an occasional paper in Russian or Bohemian was read. English, as usual, fared the worst of the three; but even French, much to the pained surprise of those whose mother tongue it was, was far less in evidence than German. Our Gallic confrères have hitherto regarded the language question with languid interest, never dreaming that the supremacy of their own speech could be really disputed, and now it is a rude shock to find themselves relegated to a second place.

The need of a universal language was recognized by the president of the Moscow congress, Professor Sklifosovsky, who devoted a considerable portion of his opening address to this subject. A great, if not the greatest obstacle to medical progress, he said, was the want of a common speech by which scientific men of different nations could communicate with each other. This lack was felt by all medical men, but nowhere more than in Russia. Russian men of science were obliged perforce to have at least a reading acquaintance with the leading tongues of western Europe, but they could never hope that their own language would be studied by foreigners, and consequently the great mass of Russian literature would ever remain a sealed book to the rest of the world. The amount of scientific work being done in Russia was something enormous, but it was absolutely unknown to outsiders, and it would remain unknown so long as its history was clothed in Russian garb. The speaker was not content with generalities, but proposed the appointment of a committee to draft a preliminary syllabus on the subject of an international language, to be brought up for consideration at the next congress.

Another Russian, Dr. L. Samenhof, of Grodno, has made a novel proposal looking to a possible solution of the question. Assuming that there is no dispute as to the desirability of a common medium of international communication, he offers a suggestion whereby an agreement can be reached regarding the selection of the language to fulfil this honorable office. His plan is simply to put the question to vote, after opportunity for free discussion has been given to all who may care enough about the subject to commit their arguments in favor of one or another language to paper. All such are requested to send to Dr. Samenhof an article embodying the arguments in support of the adoption of one particular language. All these essays, which must be signed with the name and address of the author, will be published in book form and sent to each of the contributors. Some months after the book has been issued votes will be received from the subscribers, and according to the majority of votes will be decided what language shall be adopted as the international one. Of course this decision will be binding only upon those who take part in the proposed discussion, and perhaps not even on them, yet no doubt the result of such a vote would have great weight in influencing any committee which might be appointed to consider the question as it affects the international medical congresses. We wish Dr. Samenhof every success in his laudable undertaking, and hereby cast our vote in advance in favor of the language chosen by the majority of the contestants.

SOME OF THE DISADVANTAGES OF A MODERN BATTLESHIP.

THE complaint has been frequently made of late that in the class of battleships now being built the sanitary arrangements are inadequate and that insufficient accommodation is allowed for the sick. The first and prevailing idea in the planning and construction of a modern man-of-war is to produce a fighting machine, while little attention is paid to the sanitary requirements of her crew. In the report of the surgeon-general of the United States navy, just published, this fact, especially in the case of the *Indiana*, is strongly emphasized. It is contended that an unnecessary amount of space below deck is devoted to storerooms, etc., which with a more complete system of ventila-

tion might be utilized for officers' quarters. The crew spaces are stated to be equally cramped, and on several occasions the inconveniences of crowding men into the lower parts of the ship have been manifest. Minor accidents requiring surgical treatment have, it is said, decidedly increased, owing to the circumstance of the almost total absence of wood in the construction of the ships, so that a fall or blow which would have been of little consequence on the old vessels is often attended with serious results on the present-day steel warships. Complaint is also made in the report in regard to the *Indiana* that the sick bay is very small for the size of the vessel and the number of the men. Not more than three persons, exclusive of the baymen, can be properly berthed in the sick bay, and it is frequently overcrowded. Its cubic capacity is twenty-one hundred and ten feet. Insufficient, however, as the accommodation is for the sick in times of peace, there can be no doubt that in case of war matters would be infinitely worse. The ordinary sick-quarters in war time would be unavailable, being unprotected by any armor. In fact, it would be impossible to find (according to the report) on board a ship of the *Indiana* type a space in any way suitable for the reception and treatment of the wounded. The suggestion made by Dr. George T. Bradley, that a necessary adjunct to every squadron would be a hospital ship, seems under the present state of affairs to be worthy of consideration. At any rate, some attempt should be made by those in authority to prepare for possible emergencies.

SOME THERAPEUTIC USES OF OLIVE OIL.

At the seventh annual meeting of the Association of Military Surgeons of the United States, Dr. M. O. Terry, surgeon-general of the national guard of this State, read a brief but interesting paper on the treatment of appendicitis by means of sweet oil. He said that for more than five years he had been treating appendicitis on a non-surgical plan, with the result that out of forty-five patients only two required operation, and all recovered. The method of treatment is simplicity itself, consisting in the exhibition at once of a cathartic, together with the giving of a "colon or high enema, fomentations with flaxseed poultices, and applications of hot sweet oil, the prolonged use of sweet oil taken internally, and a pultaceous diet." The choice of a cathartic, Dr. Terry says, is immaterial, although his own experience has led him to use castor oil and sweet oil combined, one part of the former to two of the latter. A high injection of from one-half to one pint of sweet oil is given, and followed by an enema of soapsuds. Sweet oil is also given internally in the dose of one-half ounce in a glass of hot water three times a day. This is continued as long as there is any tenderness in the region of the appendix.

While Dr. Terry was thus injuring the business of the surgeons in New York State, Dr. Owen F. Paget was spoiling that of the undertakers in Western Australia, by means of the same gentle remedy. This writer, in a communication to *The Lancet* of November 27, 1897, advocates the use of salad oil in the treatment of typhoid fever. During his residence in Freemantle, he says, it was his lot to attend over one hundred patients suffering from typhoid fever under the most disadvantageous circumstances, many of them being unable to obtain even fresh milk; yet he did not lose a case. Among the patients removed to the hospital, where they were properly attended to, were placed under orthodox treatment, and received suitable nourishment, the percentage of mortality was twenty in one year and eleven in another. While admitting the element of chance to a certain extent, Dr. Paget attributed his success very largely to the use of sweet oil. This he gave in the form of an enema every twelve to twenty-four hours during the first four or five days, about one-half pint being used each time. After the fifth day the injection may be given every two days, or may be discontinued entirely if the temperature is steadily falling and if the patient is having a natural movement of the bowels every day. Sometimes the injections must be supplemented by the use of oil by the mouth. Dr. Paget's endeavor is to keep the bowel flushed, using salad oil for this purpose; but the principle of his treatment is precisely the same as that of the eliminative method of Dr. Thistle, of Toronto, described in the MEDICAL RECORD of March 10, 1894.

In the closing paragraph of his paper, Dr. Pag remarks, in unconscious corroboration of Dr. Terry, that "salad oil, one pint by the mouth and one-half pint per rectum, has also given the most gratifying results in two cases of typhlitis under my care." And this reminds us that we have chanced to see no reports recently of the use of olive oil in the treatment of gall stones. Has the practice gone out of use, or is it so common that no one thinks instances of it are worthy of record?

UNNECESSARY STREET NOISES.

THERE are signs abroad that ere long there will be active and organized opposition to noises in the streets of large towns. The inhabitants of cities are beginning to appreciate the fact that the multiplicity of sounds at present is seriously detrimental to health. Some of these noises are of course unavoidable, but many of them serve no useful purpose, and would injure no interests if abolished. Among the many laws and ordinances relating to sanitation, it seems unaccountable that the question of street noises does not hold a more prominent place, and that steps should not be taken to do away with, or at least to lessen as far as possible, the ceaseless din of a large city. Physicians are too well cognizant of the disastrous effects of harsh noises to certain patients, and surely a vigorous crusade inaugurated to remedy this evil would be attended with the most beneficial results. Opinions differ as to whether the noises are worse in New York or in London; but which of the two cities can lay claim to the unenviable reputation is outside the question. The point to be settled is, what means should be employed to abate the nuisance? London has already taken the initiative, and is resolved to put down with a strong hand all unnecessary street sounds.

This is an example that should be followed by New York and the other large cities of the old and new worlds. It may not be too much to hope that electricity will solve the difficulty, and that in the ideal town of the future traction and locomotion will be both noiseless and clean. In the mean time all that can be done should be done.

EARLY WRITERS ON SMOKING.

The fact has been discovered that Shakespeare never mentions smoking or makes the slightest allusion to the habit. This is the more curious, as most of his contemporaries, Ben Jonson, Decker, and others, discuss the then new fashion at length, and the humorist and satirist of the time lost no opportunity of deriding and making game of the votaries of the weed. The tobacco merchant was an important personage in the time of James I. The Elizabethan pipes were so small that when they are dug up in Ireland the poor call them "fairy pipes." King James himself was one of the most virulent opponents of the habit, and in his ludicrous "Counterblaste" calls it a vile and stinking custom, "borrowed from the beastly, slavish Indians—poor, wild, barbarous men—brought over from America and not introduced by any worthy or virtuous or great personage." He argues that tobacco is not dry and hot; that its smoke is humid like all other smoke, and is therefore bad for the brain, which is naturally wet and cold. He denies that smoking purges the head or stomach, and declares that many have smoked themselves to death.

THE HEALTH-BOARD BILL.

We learn that gentlemen attached to the laboratory service of the health department have been circulating petitions adverse to senate bill No. 5, and have obtained many signatures, chiefly gained by representing that in the event of the passage of the bill the laboratories would be closed and the scientific work of the city be broken up. When asked how this would be brought about, they reply that it is the profit on the sale of antitoxin that enables this and other work to go on, and that if this source of revenue were cut off the board of health would be unable to secure suitable appropriations from the city authorities. We believe this fear is groundless. However that may be, the argument used is certainly a severe reflection on either the intelligence or the humanity of the mayor and the board of apportionment.

Others express the fear that if the board of health discontinues the sale of antitoxin one or two manufacturers may combine and raise the price beyond the reach of any but the affluent. Our city health board now sells it to the trade, we believe, at a discount of ten per cent., and in some instances at twenty per cent.; and yet at even these discounts and with extensive gratuitous use among the poor, there would still appear to be a considerable margin of profit in the manufacture. This certainly would invite fresh investment of private capital, and this, with the four or five existing domestic plants and the product of several European manufacturers, would result in a wholesome competition that would keep the price within the bounds of reason and justice. On the first introduction of antitoxin the price was high, but this was due to the unreversible law of supply and demand. The supply was small; the demand was great. Just so, a few years ago, there came a sudden demand for antipyrin, and the price went up almost to that of gold. In a few weeks prices settled down to the normal. So it would be with antitoxin.

News of the Week.

Experts in Criminal Trials.—Assemblyman Kelsey has introduced a bill in the New York assembly, providing for the appointment and examination of medical expert witnesses. Whenever it is made to appear to the court that the trial of issues will probably require the introduction of medical expert testimony, the court may, upon application of either party in the action, appoint such number of experts as the court shall deem proper, not less than three or more than five. Such experts shall in all cases be persons skilled in medical and surgical science, or in both, and shall be duly admitted to the practice of medicine in the State of New York, provided that in special and extraordinary cases the court may in its discretion appoint such expert persons resident in other States and duly qualified and admitted to practise medicine in the State where they reside. Each expert witness so appointed shall receive such compensation as the court shall prescribe, which shall not be less than $10 nor more than $100 per diem while in actual attendance upon such trial, and mileage the same as is allowed to other witnesses, which shall be paid by the county.

The Determination of Sex.—Dr. Schenk, of Vienna, who was reported as saying that he had discovered the secret of sex, states that he has been misreported. He simply made an assertion in the course of a lecture that it was possible to a certain extent to correct nature in the case of a woman who has become the mother of five or six girls in succession. He did not even announce it as a discovery—a newspaper correspondent, to whom one of the students mentioned the subject, being responsible for the noising abroad of the observation and its exaggeration. The result of this has been that the professor is deluged with letters from women all over the world, who want to know how to get boys.

The Plague is still prevailing in virulent form in Bombay, the number of deaths for the week ending January 26th having been eight hundred and thirty-four. The disease has recently invaded Sinnar, and the attempts of the authorities to enforce isolation excited a riot, in the course of which an apothecary was killed and a constable wounded. The temporary hospitals were wrecked and the quarantine camp was set on fire. The mob was dispersed only after the police had fired into it. The number of deaths in Sinnar up to January 31st numbered fifty-three.

The Antivivisection Bill.—Senate bill No. 1,063, which is the bill to strangle scientific investigation in the District of Columbia, introduced by Mr. Gallinger, is the subject of numerous letters from the physicians of the country to the senators of their respective States. Physicians everywhere have been urged to put the pressure on their congressmen, and they are doing it. The antivivisectionists are also making every effort to secure the legislation they desire.

The Insane in Pennsylvania.—The increase in the number of the insane in Pennsylvania, nearly six hundred annually, is causing much embarrassment to the authorities. The total capacity of the State hospitals is about forty-five hundred, and they now contain fifty-six hundred. There are also more than twenty-five hundred insane inmates of the almshouses in the State. It is proposed to adopt the Wisconsin plan of county asylums for the chronic insane, which has been in operation sixteen years and has been found to be of great utility.

Medicine in Modern Fiction.—In the article on "The Modern Novelist and Medical Subjects," in a recent number of the MEDICAL RECORD, credit should have been given to Dr. J. J. Morrissey for some of the observations incorporated in the text, which were taken from a current issue of the *Catholic World*. The omission was due to an oversight, and with no intention of ignoring the excellent work of the scholarly author.

Obituary Notes.—DR. HENRY SPALDING DEAN, of South Coventry, Conn., died on January 15th, of disease of the heart, at the age of seventy-five years. He was a graduate of the Jefferson Medical College in 1852. He leaves one son.—DR. GAMALIEL GILLIS, of Montague Bridge, Prince Edward Island, died on January 4th, after an illness of four months' duration. He was forty-five years of age, and was a graduate of the University Medical College, New York, in 1885. He leaves a widow and five children.—DR. S. W. VAN DUYN died in Plainfield, N. J., on January 25th, at the age of sixty-one years. He was a graduate of the University Medical College, New York, in the class of 1865.—DR. LEWIS FRENCH, member of the hospital staff of the Connecticut Home for Soldiers, died at his home at Noroton, Conn., on January 27th. He graduated from Trinity College in Hartford in 1879, and from the University Medical College, New York, in 1883, and for eighteen months thereafter he was on the medical staff of St. Catharine's Hospital, Brooklyn.—DR. GERHARD CHRISTIAN PAOLI, of Chicago, died at his home in that city on January 29th, at the age of eighty-three years. He was born in Sweden and came to this country over fifty years ago. He obtained a medical degree from the Rush Medical College in 1866.—DR. ISAAC MASSEY, of West Chester, Pa., died on January 31st, in the sixtieth year of his age. He was a graduate of the Jefferson Medical College in the class of 1864. He was a member of the Pennsylvania State Medical Society, of the Chester County Medical Society, and of the College of Physicians of Philadelphia. He was one of the attending physicians of the Chester County Hospital.—DR. SAMUEL P. HAMED, who was a graduate of the College of the City of New York in 1868, died on January 18th, at Woodbridge, N. J., from œdema of the lungs, caused by aortic disease. He had practised in Woodbridge since his graduation, and was at one time coroner for Middlesex County.

A Remedy for Depopulation in France.—The mayor of a small commune in France has shown the way to stimulate the fathers and mothers of France to aid in the elevation of *la patrie*, by offering a reward of 100 francs for every child born in lawful wedlock of parents resident at least one year in the place.

Reduced Death Rate in New York State.—According to the recently issued bulletin of the New York State board of health, the number of deaths in the State during 1897 was 117,075. This is 3,600 less than in 1896, and is the smallest mortality reported since 1889. The death rate for the year was 18.50 per 1,000 population; that of 1896 and also of 1895 was 19; of 1894, 18.75; of 1893, 19.3; of 1892, 20.78; of 1891, 21.43; and of 1890, 19.65. The decrease has been chiefly in the cities, the rural mortality having relatively increased. The infant mortality was also lower than usual, 32.6 per cent.

The Houston County (Texas) Medical Society, at a meeting held in Crockett on January 14th, adopted resolutions protesting against the occupation tax imposed upon physicians of the State by the legislature of 1897. A resolution was also passed urging upon the legislature the enactment of a law providing that some amount not less than $25 be declared as exempt from chattel mortgage, in case of the death of the mortgagor, the same to be preference claim for medical services. At this meeting Dr. S. J. Collins, of Lovelady, was elected president, and Dr. J. L. Hall, of Crockett, secretary.

Reported Return of Yellow Fever.—It is reported that three cases of yellow fever have been discovered on a plantation near Edwards, Miss. Dr. Carter, of the Marine Hospital service, has been sent to investigate the report. There has been no yellow fever at Edwards, as far as known, since December 1st.

Woman's Hospital of Baltimore.—The statement made that Dr. Robert T. Wilson had been elected chief surgeon of the Woman's Hospital of Baltimore, to succeed his father, the late Dr. H. P. C. Wilson, was strictly true; but for fear that injustice may be done to Dr. William T. Howard, who is also chief surgeon, we are asked to state as a matter of history that when this hospital was founded, Drs. Howard and H. P. C. Wilson were made chief surgeons and divided the service, and each had two assistants. After Dr. Wilson's recent death, the lady managers passed a resolution requesting the board of directors to elect Dr. Robert T. Wilson to the place made vacant by his father's death, should it be agreeable to Dr. Howard, and it was accordingly done. Inasmuch as the Woman's Hospital has a place in the medical history of Baltimore, it is thought right that this matter should be clearly stated.

Dr. William H. Welch, of Johns Hopkins Hospital, has been appointed by the governor of Maryland a member of the State board of health, and has accepted the position. Dr. Welch at first declined the appointment, but was induced to reconsider it.

Dr. C. Birnie, of Taneytown, Md., has been appointed on the State lunacy board.

The Editor of the "British Medical Journal." —The council of the British Medical Association, at a meeting held January 19th, unanimously elected Dr. Dawson Williams editor of the *Journal*. Dr. Williams has been assistant editor for the past seventeen years, and had full editorial charge during Mr. Hart's absence. Dr. Williams is well and favorably known outside of journalism for his excellent work, especially in the subject of the diseases of children. He became known personally to many of the American profession during the Montreal meeting of the British Medical Association, which he attended in the interests of the *Journal*. We congratulate both Dr. Williams and the association upon the excellent choice of the council. At the same meeting Mr. C. Louis Taylor, for the past eleven years subeditor, was appointed assistant editor to succeed Dr. Williams.

The County Society and Dr. Roosa.—At the special meeting of the Medical Society of New York, held Monday, January 31st, a motion to censure Dr. Roosa for statements made in a daily paper, pertaining to the action of the committee on legislation regarding appropriations for private charities and alleging irregular proceedings on the part of the society, was, after a lively discussion, duly declared lost.

An Association of the Alumni of Randall's Island Hospital was organized on January 18th. The following officers were elected: *President*, Dr. Frank Van Fleet; *Vice-President*, Dr. Robert Lewis, Jr.; *Secretary*, Dr. David T. Marshall; *Treasurer*, Dr. L. K. Neff.

Akin to Murder.—This was the term employed by Judge Wofford, of Kansas City, to characterize the doings—or rather lack of doing—of Christian scientists, in attempting to cure grave diseases. A Mrs. Baird was fined $50 for not reporting a case of diphtheria, which resulted fatally under her scientific ministrations.

The St. Louis Laryngological and Otological Society was organized on December 27th. It is composed of those physicians of St. Louis who limit their practice to the treatment of diseases of the nose, throat, and ear. Dr. J. C. Mulhall was elected *President*, Dr. J. B. Shapleigh *Vice-President*, Dr. F. M. Rumbold *Secretary*, and Dr. A. S. Barnes, Jr., *Treasurer*, for the year 1898. Meetings will be held monthly.

American Dermatological Association.—The date of meeting, which was to have begun on June 7th, has been changed on account of its conflicting with that of the American Medical Association. The association will meet at Princeton Inn, Princeton, N. J., on May 31st and June 1st, and at the New York Academy of Medicine on June 2d.

Warning.—A certain amount of misrepresentation appears to go with the solicitations being made in connection with a history of this city in which physicians are supposed to be interested. *Verbum sap.*

Cattle Disease in Nebraska. — Stockmen near Hooper, Neb., are complaining of heavy losses from a disease which has broken out recently among their cattle. The affection is denominated foot rot, and is said to be exceedingly contagious and very rapidly fatal.

The St. Louis Medical Society.—The following officers were elected at the annual meeting of this society, held Saturday, January 8, 1898: *President*, Dr. Joseph C. Mulhall; *Vice-President*, Dr. Amand Ravold; *Recording Secretary*, M. F. Engman; *Corresponding Secretary*, Dr. A. S. Barnes, Jr.; *Treasurer*, A. R. Kieffer.

"The North American Journal of Diagnosis and Practice" is the name of a new monthly medical journal, born in January in St. Louis. The editors are Drs. C. H. Powell, J. G. Ehrhardt, and A. R. Kieffer, who announce that their publication will be in no sense the organ of any medical college or clique, but will be devoted to the interests of the individual physician.

Nursing in Tuberculosis.—On January 15th, a training-school for nurses was opened at the Loomis Sanatorium at Liberty, N. Y. The opening-class had thirteen members. Miss Helen Kimber, a graduate of the Bellevue Training-School, is the superintendent. The opening-address was made by Dr. H. P. Loomis, of New York. While these nurses will receive regular training, such as is given in other schools, special attention will be paid to instruction in the care of cases of tuberculosis.

Obituary.

THEOPHILUS PARVIN, M.D., LL.D.,

PHILADELPHIA, PA.

Dr. Theophilus Parvin, professor of obstetrics and gynæcology at the Jefferson Medical College, died at his home in Philadelphia, on January 29th, at the age of sixty-nine years. Dr. Parvin was born at Buenos Ayres, Argentine Republic, where his father was a missionary, on January 9, 1829. He received his early education in Philadelphia, and subsequently at Indianapolis, where he was graduated from the University of Indiana in 1847. He then returned to Philadelphia, where he took a course in medicine at the University of Pennsylvania, obtaining his degree from the medical school there in 1852. He practised for a while at Indianapolis, and was afterward for a time surgeon on a line of sailing-packets between Philadelphia and Liverpool. He filled chairs successively at the Ohio State Medical College, the University of Louisville, and the Indianapolis Medical College. He was called to the chair of obstetrics and gynæcology at the Jefferson Medical College in 1883.

Professor Parvin was a close student and an accurate scholar, and early won for himself an international reputation as an authority in his chosen branch. He was an honorary member of several obstetrical societies in Edinburgh, Berlin, and elsewhere.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 20, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

THE meeting was in charge of the section on neurology and psychiatry.

Parental Diabetes as an Etiological Factor in Insanity.—DR. E. C. SPITZKA read a paper with this title. He said that it had been long known that diabetes in all its forms played an important rôle in family histories. Clouston had described two cases in which he established a direct relation between the glycosuria and the mental aberration. Dr. Savage, of the Bethlehem Royal Asylum, stated that diabetes sometimes alternated with neuroses. In the climacteric neuroses diabetes also played a part. The cases of mental disorder which he had found in the direct descendants of parents numbered forty-six, of which thirty-two were in males and fourteen in females. Thirty-four out of the forty-six patients died in advanced dementia or were in a hopeless condition. In thirteen the transmission was from the paternal, and in thirty-five from the maternal side. Altogether the forty-six were children of forty-one parents. It was worthy of note that of the thirty-two, twenty were of the Jewish race. After reading a number of detailed clinical histories, showing the family relationships and tendencies, and their bearing upon the subject under discussion, Dr. Spitzka said that eleven years ago he had studied two hundred and two patients in an insane asylum, the victims of self-abuse. Of this number, sugar was noted in the urine in fourteen per cent., and, strangely enough, the urine was frequently of moderately low specific gravity. The speaker then pointed out that it was a very common mistake to attribute the condition of these patients to self-abuse, although undoubtedly they very frequently indulged in this vicious habit, and were injuriously affected by it much more than was any other class. The sexual manifestations of these patients are not due to strength, but to abnormalities and weaknesses. Absolute impotence in a diabetic should be regarded as a blessing in disguise, not only to the public, but, above all, to the diabetic himself.

DR. W. H. DRAPER said that he had been long interested in the subject of diabetes and allied disorders. At first he had regarded diabetes as a chemical disorder, for it was an attractive theory until one became impressed with its utter incompetence. It did not seem to him that there was much question now about diabetes being a nervous disease; as to the exact lesions and their location, we were not well informed. Its phenomena were not to be explained by a simple defect in the process of digestion; its origin must be sought in a neurosis. This evening we had been told of certain psychoses observed in diabetics, and it was easy to recognize that these psychoses were important elements in the disease. Perhaps the most striking feature of the disease was the great mental and physical prostration. The advocates of the chemical theory explained this by supposing that the food was not absorbed, but went to waste, and that therefore the force which it was capable of yielding was lost. It was a fact that as soon as the excretion of sugar by the kidneys was diminished, the health and vigor of the individual improved. Most authors recognized the fact that gout, lithæmia, and glycosuria were, so to speak, convertible diseases; that is to say, any one of these diseases might occur in a family and be transmitted. Another interesting fact was that certain neuroses which were well known to be gouty, were also liable to occur in diabetes. An example was to be found in spasmodic asthma, which was a common disorder in gouty families. Dr. Draper said he could not remember having met with a case of insanity associated with diabetes. For a number of years he had had under his observation a case of insanity of adolescence, in which there had been a marked gouty tendency and a most obstinate lithæmia. There was a distinct family history of gout, and a distinct history of a gouty habit in the individual and in the immediate members of his family.

DR. B. SACHS said that the reader of the paper had set himself a very serious though interesting problem to solve. Personally he had some doubts regarding the intimate connection between diabetes and the forms of insanity alluded to in the paper. It seemed to him that diabetes was not only a neurosis, but was a neurosis of the second half of life. He questioned, therefore, whether it was entirely correct to make this neurosis responsible for many of the forms of insanity, unless statistical inquiry proved that the parents of the subject afflicted with some form of insanity had been afflicted with the disease before that individual had been born. It would probably not be difficult to show that Bright's disease occurred in a considerable number of the ancestors of a given insane individual, and probably the same could be done regarding cancer and various other maladies. His personal experience showed a very frequent history of diabetes in the families of insane patients, but it had never impressed him that this proportion was greater than in the case of some other serious diseases—such, for example, as Bright's disease. The occurrence of epilepsy or of idiocy in the descendants of those directly afflicted with diabetes before the subject was born was a common experience. He would like to ask the reader of the paper whether the forms of insanity he had observed in the descendants of diabetics were those classed usually as degenerative, or would he include the acute insanities. In studying the statistics given regarding the Semitic race, their greater struggles for existence, greater hardships, and peculiar mode of life should be taken into consideration.

DR. EDWARD D. FISHER said that in the descriptions of diabetes given outside of the field of mental disease, not much reference was made to insanity, nor was there much reference made to the occurrence of diabetes in the insane. If Clouston referred only to two cases in his large experience, this in itself would indicate that diabetes was an insignificant factor in the etiology of insanity. In some reported cases of diabetes occurring in the insane, it was stated that on the development of the insanity—usually melancholia—the diabetes frequently seemed to cease, and that on recovery or improvement in the mental condition the sugar reappeared in the urine. He could not understand this, and would like Dr. Spitzka to shed more light upon it. Unless it could be shown that special forms of insanity followed diabetes, it did not seem fair to argue that insanity in individuals having diabetic parents was the result of the diabetes. We would probably find, in a general way, that diabetes, like intemperance, might be a factor in producing maldeveloped children, but he did not believe in any more specific connection between the two.

DR. N. E. BRILL asked if inquiry had been made into the ancestral condition of the parents. If it could be found that the parents of these diabetics had been insane, the appearance of the insanity in the grandchild might represent a psychical atavism, so to speak, and the diabetes in the intermediate parent would simply represent the transmission of this degenerative taint. He thought too much stress had been laid upon diabetes as a neurosis. Although this view had been

held very generally in the past, there was now a tendency to return to the chemical theory. In the last two years Italian observers had noted the occurrence of diabetes in connection with disease of the pancreas. He would also like to ask Dr. Spitzka if he had excluded syphilis in the parent in the cases considered in his paper.

Dr. Thomas E. Satterthwaite said that a little over twelve years ago, in a paper based on a study of forty cases of glycosuria, he had stated that the nervous system must be held responsible for this disease. For the cases in which glycosuria had been produced by puncture of the fourth ventricle, extirpation of the superior cervical ganglion, pressure of tumors and clots on the brain, etc., he had offered in explanation the popular theory that it was due to vasomotor paresis of the vessels of the liver. At the same time he had shown that the action on the hepatic vessels might be reflex, and that direct stimulation of the liver and pancreatic disease might give rise to glycosuria. In the light of recent experiments another view might be held—*i.e.*, that irritation of the liver caused the discharge of glycogen in that organ. He believed that future experiment would show still other varieties of diabetes. Among the contributing causes found in a list of forty-five cases under his observation were mental anxiety in six, injury to the head in three, severe neuralgia in two, sexual abuse in two, overwork in one, abuse of opium in two, and a diabetic mother in one case. He recalled a single instance in which a diabetic woman under his care had epilepsy and insanity in her children, but he had reason to believe her diabetes had not developed until after the menopause.

Dr. L. C. Gray said that the great merit of the paper lay in the demonstration of the marked connection between diabetes and insanity, and he was astounded to learn that so many cases could have been seen by one observer. Although it had long been a routine practice with him to have the urine examined, he had very rarely met with such cases. He would like to know whether in the cases reported the sugar had been present in large quantity, and whether it had been present constantly or intermittently.

Dr. Max Einhorn said that he had been surprised to find that von Norden made the statement that in the Berlin clinic, of the 23,000 patients in the clinical wards, from 1890 to 1893, there was 1 diabetic to about 355 patients; while during the same period, of the 2,535 patients in the psychiatric clinic, there was not one diabetic. He was inclined to favor the neurotic theory of diabetes, and the fact that excision of the pancreas caused diabetes did not prove that the disease was not of neurotic origin.

Dr. A. W. Ferris referred to the case of a Hebrew woman, forty-seven years of age, the mother of one child, in whom diabetes had been discovered in 1893. She had been through the usual experience of a diabetic, and for three months had had melancholia with suicidal tendency. For the last two years the only psychical disturbances had been intellectual depression and a weakened judgment, with impaired memory. Her father fell dead suddenly of what was supposed to be heart disease. Her mother died of "softening of the brain," after having been partially paralyzed for some years. Of the patient's three brothers, none married. One of these brothers had convulsions for the first three years of life, and at seventeen years had acknowledged epilepsy, which continued for ten or twelve years. A son of the patient's sister had epilepsy for some years, and now, at the age of sixteen, has external strabismus and talks like a child of two years. A niece of the patient's father was reported to have recovered from diabetes. The patient's mother's brother also had diabetes for many years. One of his daughters had myxœdema, and one son had become insane.

Dr. Spitzka, in closing, said that the elements making up the claim of his paper were these: (1) the coincidence in the clinical form; (2) coincidence in two sets of individuals and independent statistics—the one beginning eighteen years ago, from one point of view, and the other continued since, from a different point of view, and dealing with material derived from two separate sources of information. One represented the statistics of a large asylum, containing all classes of the population; the other represented the experience of a single practitioner. Yet both had led to the same conclusion regarding the same form of insanity—a distinct and well-marked one, according to most observers—occurring in the same class and under the same circumstances. Of course this might be a mere coincidence, but the same figures in sex and age relations were presented. Syphilis had been excluded in all his cases, so far as it was possible to do so. He had always found diabetes to be a more or less neurotic disease, and he did not pretend to distinguish between the different varieties, such as pancreatic diabetes, etc.

SECTION ON SURGERY.

Stated Meeting, January 10, 1898.

W. W. Van Arsdale, M.D., Chairman.

Amputation at Shoulder for Melanotic Sarcoma of Shaft of Humerus.—Dr. A. L. Fisk presented a man who had strained his arm last March while lifting a piano. In May, while jumping upon a wagon he felt something give way, and since then had been unable to use the arm. When he was first seen, October 1st, there was a false point of motion, and radiographs showed distinctly the new growth involving the shaft. On October 21st, Dr. Fisk performed amputation at the shoulder-joint. The man was up on the fifth day, and made a rapid recovery. The pathologist reported the growth to be a melanotic mixed-cell sarcoma with fibro-sarcomatous portions.

Excision of Extensive Lupus of Face, Followed by Thiersch's Skin Grafts.—Dr. Fisk also presented a woman who had been sent to him in January, 1894, with a large ulcer on the left cheek. She had had this for ten years, and it had been treated by caustics and by curetting. It had steadily grown worse under all treatment. He excised the skin, including the margin of the ulcer, and covered the raw surface with Thiersch skin grafts. Occasionally since then small ulcerating spots had developed, but had yielded readily to applications of monochloracetic acid. The result was now very good, the grafted skin being only a shade lighter than other portions. The clinical diagnosis had been lupus.

Dr. B. Farquhar Curtis, on behalf of Dr. Van Arsdale, stated that the latter had had a patient with lupus of the eyelid, which had existed for many years, and which had finally destroyed the lid. He had excised the lids, removed the globe of the eye, and grafted the interior of the orbit and the exterior also with Thiersch grafts. When the patient was last seen the result had been excellent.

Fracture of Patella Treated by Massage.—Dr. H. Lilienthal presented a young woman who had been admitted to the Mount Sinai Hospital about ten weeks ago. On the day before admission she had sustained a comminuted fracture of the right patella. One of the fragments, the lower one, consisted of about one-third of the patella, and the other portion of the patella was split into two large pieces. One of these latter was freely movable. Dr. Lilienthal said that he had previously tried the massage treatment in

two cases, and, recognizing that the chief point was to secure perfect function and not necessarily bony union, the treatment had seemed to offer special advantages. In one of the previous cases so treated the result was excellent, and the patient had been presented to the New York Surgical Society. The other case was that of a young man whom he had not seen for some days after the injury. This man had also been exceedingly well, and at the present time was able to ride a bicycle and do whatever any one else could. In the patient to be presented there was a slight hollow between the two fragments; flexion and extension were perfect; the patient could stoop and kneel, and hop on the injured limb. She had been out of bed and walking eight days after the accident, and her life had not been jeopardized by an operation.

The Method.—The speaker said that he had first read of the method in Koenig's "Surgery," where it had been credited to a Dutch surgeon. It consisted in bandaging the limb and placing it on an inclined plane so as to relax the quadriceps as much as possible. As soon as the first shock was over, the massage was commenced. This required two persons—a physician to hold the fragments together, and a massage operator. The massage began at the body with upward strokes, and was carried downward to the knee. The region of the knee was rubbed very gently. This treatment had to be repeated twice daily, and the most attention was given to the quadriceps. After each treatment the lubricant should be rubbed off and the limb cleansed with ether, and the fragments approximated by adhesive-plaster strips, before the limb was returned to its former position on the inclined plane. Generally after the third or fourth day half an hour would be required for each treatment. On the eighth day it was perfectly safe to allow the patient to go about with a light starch splint on, to prevent flexion. The patient might be allowed to walk about as desired, with the aid of a cane only. The splint was split down the front, so that it could be readily removed for the massage. In the case presented, gentle flexion was begun on the twelfth day. In his opinion it would have been better if this had been begun a little earlier. The flexion should be gradually increased, never causing more than very slight pain. After the massage treatment had been kept up for six weeks, the patient should be cured.

Dr. George Woolsey said that he had seen one of the cases treated by Dr. Lilienthal according to this method, and the result had certainly been excellent. Personally, he had treated a number of fractures of the patella in this way, in all cases with a very good functional result. His method differed only slightly from that described. The massage was performed only once a day on account of the time consumed, and he also used elastic compression in the early part of the treatment, for it was known that it was not so much the quadriceps muscle as the quantity of extravasation in the joint which prevents the approximation of the fragments. He had never obtained union so nearly bony as had occurred in one of Dr. Lilienthal's cases.

Dr. A. M. Phelps thought the expression "massage treatment" was misleading, for these cases had also been treated with the retentive appliances used by all surgeons, and the massage was used simply to increase the circulation. It should be understood that the general treatment was about the same as formerly, and that the nutrition was merely aided by massage. He was doubtful regarding the permanency of the good results obtained in cases of fracture of the patella from any treatment short of a surgical operation, for the reason that the capsule fell in between the ends of the bone, and bony union never took place. According to his experience, these ligaments invariably stretched after one, two, or three years, becoming greatly elongated. A long ligament tended to stumbling and fracture of the opposite patella—a condition not infrequently met with. He believed, therefore, that it was better to cut down upon the patella, remove the foreign body from between the ends of the bone, and secure bony union by wiring. Such a result would be permanent. Intermittent elastic compression had been used by a number of surgeons for the last two or three years, and it seemed to increase the nutrition of the parts and shorten the period of repair.

Dr. Van Arsdale asked if there had been much effusion in this case, and how the result compared with those which Dr. Lilienthal had formerly wired.

Dr. Lilienthal replied that there had been only moderate effusion. In one of the other two cases the effusion had been so great that he had aspirated the joint. Aspiration and elastic compression were both part of the Dutch treatment already referred to. He had used elastic compression in all of the cases, employing rubber in the first one and flannel in the last two. He could not agree with Dr. Phelps that this was merely a slight modification of old methods of treatment. It was very seldom that a patient with a fractured patella would be able to walk around by the eighth day. He was quite sure that massage had a twofold advantage, viz., (1) the getting rid of the effusion, and (2) the passive motion produced at the same time. He had wired a number of fractured patellæ and had never had an accident, yet a surgeon whom he knew to be careful and skilful had had a fatal case under this treatment. There did not seem to him to be any reason for taking such a great risk when an excellent functional result could be obtained by a safer method.

Dr. Phelps added that there had undoubtedly been some deaths after wiring of the patella, but they had been exceedingly rare. On the other hand, it was not uncommon to meet with cases in which very dangerous falls had resulted from the long ligament and an ununited patella.

Stone Impacted in the Deep Urethra from Childhood.—Dr. Lilienthal also presented a young man who from the fifth or sixth year had had frequent and painful urination. This had grown steadily worse, but he had never had complete retention. About one month before he came under observation the pain had become very severe, and had also radiated to the rectum. On examination the diagnosis of impacted stone in the urethra was made. Through a suprapubic incision, about one inch long, the finger was able to feel a rough stone, which was firmly fixed. During the manipulations the stone broke off. Then, with the finger as a guide, an instrument was introduced and the stone extracted. It was of irregular shape, consisting of two portions joined together by a narrow isthmus. One part was in the urethra and the other projected into the rectum. A soft depression was felt in the rectum, and on massage of the rectum at this point, having him urinate afterward, the urine was found to contain a plug of mucus. This came from the portion of the rectum into which the stone had projected. This massage had been kept up for a time, and now there was no longer any such discharge of mucus.

Dr. Curtis said that it seemed very evident from the shape of this stone that it had developed in the prostatic sinus—a very common situation for these urethral stones. He recalled removing some years ago a somewhat larger stone, but of the same general shape. A part of the stone had lain in the bladder and a part in the prostatic urethra, which it had dilated. These stones developing in the prostatic sinus almost invariably have this shape; they probably grow backward into the bladder, thus giving rise to the constricted neck.

Dr. James P. Tuttle asked what had led Dr. Lilienthal to remove this stone by the suprapubic operation instead of by the safer perineal operation. The pocket from which the stone had been taken was likely to become a receptacle for urine and urinary sediment, and so form a starting-point for another stone, or else invite infection, suppuration, and in time the formation of a recto-urethral fistula. There were such cases on record. The successful result in this case from massage was fortunate, to say the least.

Dr. Lilienthal said that knowing that the stone was firmly impacted, and suspecting that a portion might be impacted in the bladder also, he had selected the suprapubic route as the preferable one. The shape and friability of the stone seemed to prove that this choice was a wise one.

Recovery after Pure Infection with the Bacillus Aerogenes Capsulatus.—Dr. J. F. Erdmann presented a boy to show a recovery from a pure infection with the bacillus aerogenes capsulatus. He recalled the fact that some months ago he had read a paper on this subject before this section, and had drawn some conclusions regarding the treatment. The boy is eleven and one-half years of age. On August 19th, he fell six or eight feet, producing a compound fracture of the radius and ulna. On the following morning he had had a chill, and that night there had been marked gangrene of the fingers. At this time, when the speaker had first seen him, there had been a condition of marked toxæmia. The wounds of the compound fracture were surrounded by a blackened and crepitating area, having a pronounced odor, and the gangrene had extended up to the insertion of the deltoid on the outer side. On the inner side there was redness extending into the axilla. Over the entire posterior surface there was marked crepitation. After the infusion of saline solution the arm was rapidly amputated, without any regard to flaps, in order to do the operation as quickly as possible. By the next morning his delirium had gone, and he was anxious to get up. On the fourth day he was discharged. Dr. Erdmann said that he had learned that recently there had been a recovery from infection with this bacillus—possibly a pure infection—but the case just presented was the first authentic instance of pure infection with this bacillus and subsequent recovery.

Fracture of Patella; an Artificial Joint.—Dr. A. M. Phelps presented a patient who had sustained a fracture of the patella the first week of last August. He went to St. Vincent's Hospital, and was treated there and discharged. In the second week of October he again fractured the patella, and was sent a week later to the City Hospital. When seen a few days later, the limb was enormously swelled and the joint filled with fluid. The appearances were those of purulent effusion. Accordingly on November 7th Dr. Phelps operated upon him. The case was presented because of the novel procedure adopted. On opening the joint it was found that the synovial sac had been totally destroyed, that the cartilages of both the tibia and fibula had been almost entirely destroyed, and that complete excision seemed necessary. After he had succeeded in removing all of the diseased structures, the parts looked so much better that he had resorted to a procedure used by him in two or three cases, *i.e.*, the endeavor to restore a normal joint by interposing some of the soft tissues between the ends of the bones, thus preventing the contact of bone with bone. He then wired the patella firmly and inserted drainage. The patient was lost sight of for a time, but returned the other day with the function of the joint preserved. Dr. Phelps said that the reason he had resorted to this procedure in the present case was that in operations for angular deformity of the hip he had succeeded in obtaining a very good artificial joint. Last fall he had adopted the same plan instead of amputation in a case of ankylosed finger. Two incisions had been made, one on either side of the finger, the bones divided, and then one portion was made convex and the other concave, so as to simulate the natural surfaces of a joint. The arterial supply having been left intact, he turned in the flaps of cellular tissue between the ends of the bones, and obtained an almost perfect result. He had also used this method in three cases of complete excision of the knee. In one done a year ago fairly good motion had been secured; in another the result was bony ankylosis, and in a third case motion to an angle of about 15 .

Technique.—In performing the operation on the knee, the incision is made beginning above the condyle and going along the border of the patella down to the head of the tibia on either side. This skin flap is turned down, thus exposing the underlying tissues of the knee. An incision is then made from a little below the head of the tibia, directly through the capsule of the joint, and extending, of course, underneath the patella. The tissues are next turned down on either side, and all of the diseased soft parts are removed by curved scissors. With a butcher's saw having a very fine removable blade it was possible to make two fine concave sections, thus preserving the true plane of the joint. The structures attached to the capsule of the joint are then dissected away and the lateral ligament is detached from the bone, together with the periosteum; then the tissues just dissected away are turned over the condyles and united with catgut. The lateral ligament is then brought back and fastened to the bone with pegs. The skin is finally closed. The limb is dressed at the end of ten days, and again after three weeks. From the sixth to the eighth week the patient is allowed to use the limb. The patient just presented left the hospital two weeks ago. In making an artificial articulation in cases of angular deformity of the hip-joint the same procedure is resorted to, only somewhat modified. The chisel is driven through to the neck, and the remaining portion forcibly broken through. The upper portion is then rendered concave and a portion of the gluteus muscle is turned down between the fragments. This prevents bony union.

The Best Method of Administering Schleich's Solution for General Anæsthesia.—Dr. Willy Meyer insisted upon administering the Schleich solutions on a mask by the drop method, one drop being allowed to fall upon the mask every four or five seconds, or somewhat oftener at the beginning. In order to allow the rapid dropping he had found it convenient and desirable to modify the mask rather than the dropping-bottle. The large quantity of the anæsthetic used by him at the German Hospital had been because he had employed for the most part the ordinary Esmarch mask without the oil-silk covering, which Schleich now recommends. The ordinary paper and towel mask can be employed with the new method, but it should be remembered that a sufficient though small amount of pure air must be admitted. The less experienced anæsthetizer would find the modified Esmarch mask better and safer than the towel cone. In the mask which Dr. Meyer had devised for use with this method of anæsthesia, the funnel is so arranged that the rapidity with which the anæsthetic solution drops upon the mask may be regulated to a nicety by simply turning the funnel more or less to the left. He had also found it desirable to insert a perforated metallic disk between the flannel and the oil silk, so as to facilitate the distribution of the fluid over the mask. The frame of the mask is deeper than that used for the ordinary chloroform mask, in order to avoid burning the patient's face. For greater portability the essential features may be conveniently

adapted to the folding mask of Schimmelbusch. For old and feeble persons, or children, or those suffering from bronchitis or other pulmonary disease, or for those having heart disease, it was best to use solution No. 1, but under other circumstances No. 3 was preferable, because of the strong reflexes excited during the operative manipulations if No. 1 was used. The operation should never be begun before the patient is thoroughly under the anæsthetic. Experience had shown that the corneal reflexes often disappeared before the patient had been completely narcotized. In conclusion, the speaker reiterated his belief that those who gave the method a fair trial would not willingly return to the old method with pure ether or chloroform.

Dr. J. P. Tuttle said that he had used the method in four or five cases. In two of them the recovery from the anæsthesia had been associated with an unusual degree of mental excitement, lasting from half to three-quarters of an hour. The induction of the anæsthesia and the recovery of consciousness were certainly rapid and satisfactory.

Dr. F. Kammerer said that he had used the method in thirty or forty cases, but considered this number too limited to admit of drawing any definite deductions. The other day he had had a very severe case of collapse with it, but he was inclined to attribute this accident rather to the inexperience of the anæsthetizer than to the anæsthetic itself. He had been most favorably impressed with the rapidity with which the patients, as a rule, had recovered from the anæsthetic.

Dr. Lilienthal said that he had used the mixture in only six cases. In one of these there was very persistent vomiting, lasting for two or three days. He would like to ask Dr. Meyer if the mask presented by him would not almost entirely exclude the air, and whether this was desirable. He also thought an accident might easily occur if the funnel was not so constructed as to make it impossible accidentally to alter the adjustment of the dropper. Without such a contrivance it was quite conceivable that the funnel might become shifted, and without the anæsthetizer noticing it, and a large quantity of the anæsthetic solution be poured on the mask.

Dr. Erdmann asked if Dr. Meyer deemed it advisable to use morphine or atropine previous to the anæsthetic.

Dr. Van Arsdale said that his experience had been limited, but he was sorry to say that the results had not been so satisfactory as with the older methods. All of the patients vomited, either on the table or immediately after the operation. They also coughed incessantly. He had observed two cases in which there had been quite alarming asphyxia while the patient was on the table. Quite probably these unfortunate results were due to his inexperience.

Dr. Meyer, in closing the discussion, said that in only a single case had he observed any wild excitement after the anæsthesia. Many patients are excited on coming out of the anæsthesia because of the pain, and entirely independent of the anæsthetic agent. He did not see how the anæsthetic could produce such a condition. The method, of course, did not prevent vomiting, but, according to his own experience, it had greatly reduced the proportion of cases in which vomiting occurred. Regarding the collapse, he would say that among those trying the method for the first time he had observed a tendency to deluge the mask unnecessarily and dangerously with the anæsthetic, and to this should be ascribed the occurrence of the collapse. He thought sufficient air was admitted in his mask; of course not so much was required as with the chloroform mask. As the top of the funnel was under the eye of the anæsthetizer, he should be able to notice any accidental alteration in the adjustment of the funnel. It had commonly happened that a poor quality of benzin had been furnished instead of petrolic ether having the desired boiling-point. In alcoholic subjects he would certainly recommend the administration of morphine. One of his patients had been previously anæsthetized six or seven times, sometimes with ether and sometimes with chloroform, and had had very severe vomiting in each instance. On the day following the induction of anæsthesia by the Schleich method, the patient expressed himself as being extremely pleased with the effects of the new anæsthetic.

The Asch Operation for Deviations of the Cartilaginous Septum, with a Report of Two Hundred Operations.—Dr. Emil Mayer read a paper with this title, and presented some illustrative cases. (See page 190.)

Dr. D. Bryson Delavan said that he could heartily corroborate the statements made in the paper. This operation marked a very radical and useful departure from the older and more usual methods of treatment. The reader of the paper might have emphasized a little more the excellent results of the operation as regarded the external deformity. From beginning to end the operation was highly original and ingenious; it was admirable in its conception and in its results. The operations of Steele and Adams had never become popular. The Asch operation could be completed under primary anæsthesia, with very little loss of blood, and with so little shock and damage to the parts as to challenge admiration. The profession was certainly greatly indebted to Dr. Asch for this perfected method.

Dr. W. Kelly Simpson said that he could affirm without any hesitation that it was the best method at command at present for overcoming deviations of the septum. Most of the other operations had fallen into disrepute because of the unsatisfactory results obtained. The great point was to overcome the resiliency of the septum, and to retain the latter in proper position until it would remain permanently in the desired position. It was remarkable how much could be accomplished by this simple operation, even in severe deflection of the septum. To control the hemorrhage it was convenient to introduce at the time of the operation two tubes, one on each side. The one on the concave side could be removed in a day or two. He had done the operation under cocaine, but preferred general anæsthesia. It was a simple matter to incise the septum with a scalpel, but in doing this one rarely, if ever, obtained the exact crucial incision desired, and hence it was advisable to operate only with the instruments devised by Dr. Asch. He preferred for this operation the flat tubes rather than the more conical ones, because the former exerted more uniform pressure.

Dr. Morris J. Asch said that the operation had been thoroughly described, so that it was hardly proper for him to say much about it; yet he was glad that it had been brought this evening to the attention of the general surgeons, who were not always thoroughly familiar with the recent operations of nasal surgery. His operation approached more nearly to the class of operations done in general surgery. The deformity for which it was done seemed to him much more serious than was commonly believed. It gave rise to mouth breathing and headaches, chorea, and many other nervous manifestations. He would emphasize the fact that a great many obstinate headaches could be cured in this way. He did not agree with those who stated that many of these deflections of the septum were due to traumatism; some of them were, but the larger number probably resulted from an abnormal development, either *in utero* or in the first few years after birth. The vomer originally consisted of two

bony layers, and it sometimes happened that there would be a hypernutrition on one side and consequent bending of the septum. Sometimes this condition of hypernutrition existed at more than one point, in which case there might result a sigmoid deviation.

Dr. D. H. Goodwillie said that previous to the introduction of the Asch operation he had been in the habit of doing the operation with the small cutting instruments that he used in operating upon cleft palate. The principles of his operation were essentially those described this evening, but he had found it very difficult to manage the patient and make just the desired incisions. The advantages, therefore, of Dr. Asch's instruments were very apparent. He used his own tubes of soft rubber instead of the hard-rubber ones, because he had found that after the insertion of the tube there was likely to be considerable swelling. If a soft-rubber tube was used, it would yield somewhat and give the patient greater comfort. For the control of the bleeding he found that peroxide of hydrogen was an excellent application, being both hæmostatic and antiseptic. In some cases in which there was considerable deformity of the septum, the septum seemed to be shifted over to one side and fixed there. In these cases the external deformity would be very much improved by making the incision on the upper part of the septum, so as to leave the attachment of the septum to the bridge of the nose. The septum would then slide over to its proper place, and the deformity would be reduced. It would sometimes be necessary to place a little cotton above the tube if the latter were not a large one.

Dr. Mayer, in closing, said that the great improvement in the external deformity was certainly remarkable. It was well known that one of the best hæmostatics for the nose was air. On insertion of the tubes a free current of air was quickly established and the hemorrhage was thereby checked. His experience with the soft-rubber tubes had not been satisfactory, because of the amount of irritation produced by the soft rubber. This he had not observed with the hard-rubber ones. Even when the deformity of the septum was extreme, a most excellent result could be obtained by this simple operation of Asch.

Dr. Goodwillie said that the irritation of the nose noted in the patient presented this evening was probably due to the fact that the red rubber sometimes poisons the wounded tissues. The soft rubber should be carefully manufactured, and well washed before being used.

Dr. Mayer replied that in his opinion the soreness of the nose in this patient was entirely due to the pressure of the foreign body; if it had been the result of poisoning, it would have shown itself in other parts of the nose.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Second Annual Meeting, Held in Albany, January 25, 26, and 27, 1898.

Seneca D. Powell, M.D., of New York, President.

(Concluded from page 172.)

Third Day—Thursday, January 27th.

Committees.—Committee on Arrangements.—Dr. Samuel B. Ward and Dr. William J. Nellis, of Albany; Dr. Reynold W. Wilcox, of New York.

Committee on Bylaws.—Dr. H. D. Wey, of Elmira; Dr. Nathan Jacobson, of Syracuse; and Dr. F. C. Curtis, of Albany.

Committee on Prize Essays.—Dr. J. M. Van Cott, of Brooklyn; Dr. Andrew McFarlan, of Albany; and Dr. William S. Cheesman, of Auburn.

Committee on Publication.—Dr. F. C. Curtis, of Albany; Dr. Daniel Lewis, of New York; Dr. Charles H. Porter, of Albany; and Dr. W. W. Potter, of Buffalo.

Committee on Hygiene.—Dr. Henry R. Hopkins, of Buffalo; Dr. E. H. Bartley, of Brooklyn; Dr. C. E. Bruce, of New York; Dr. J. M. Mosher, of Albany; Dr. O. W. Peck, of Oneonta; Dr. H. F. Hart, of Shrub Oak; and Dr. George Seymour, of Utica.

Committee on Legislation.—Dr. F. Van Fleet, of New York; Dr. Arthur G. Root, of Albany; and Dr. Ernest Wende, of Buffalo.

Committee on Ethics.—Dr. Evarts M. Morrell, of Yonkers; Dr. George McNaughton, of Brooklyn; and Dr. Louis A. Weigel, of Rochester.

Committee on Medical Expert Testimony.—Dr. J. B. Ransom, of Dannemora; Dr. A. Walter Suiter, of Herkimer; Dr. Carlos McDonald, of New York; Dr. Willis G. Macdonald, of Albany; and Dr. P. M. Wise, of Albany.

Treatment of Delirium Tremens.—Dr. T. D. Crothers, of Hartford, Conn., read a paper on this subject. He said that delirium tremens was a condition occurring as a result of alcoholic injury to the brain centres. There were many reasons for believing that in a certain number of cases it was due to bacteria, and in a still larger number to autointoxications of various kinds, such as those connected with the action of the kidneys and liver. It also occurred as a direct result of traumatic lesions. Post-mortem examination always showed parenchymatous degeneration of the liver and heart, acute inflammatory conditions, anæmia, and profound disturbance of the vital forces. In the treatment of delirium tremens Dr. Crothers believed that all spirits should be removed at once, and that the theory that sudden withdrawal of alcohol caused the delirium was not only erroneous, but that it had led to many deaths. The use of opium, chloral, and the bromides he considered to be equally dangerous, as these drugs, and especially chloral, did not promote the elimination of the poisons. Elimination should be the cardinal objective point of the treatment. The first requisite was the hot-air bath, or, in private practice, hot sponge or tub baths. This treatment must be kept up for two or three days, and every effort made to establish and maintain free diaphoresis. An old but very useful treatment was free catharsis by calomel and salines. Restraint should be modified, and alternated with much liberty. As a rule, the patient did better when allowed plenty of space in which to walk about and work off the muscular excitement. According to general experience, this muscular excitement lasted but a short time—rarely more than thirty-six hours—when such liberty was allowed. It should not be forgotten that muscular delirium and sweating were nature's efforts to remove the exciting causes of the disease. The classical delirium tremens of the text-books was rarely seen. Melancholia, dementia, and death were often directly the result of reckless drugging and the continuance of alcoholic stimulants.

Intratracheal Injections for Diseases of the Bronchial Tubes and Lungs.—Dr. H. S. Drayton, of New York, read this paper. He said that as far back as 1840 Dr. Horace Greer, of New York City, had announced that lung diseases could be successfully treated by local applications, but at that time his claims were met with scepticism and censure. A smoothly working aspirating-syringe, fitted with a proper laryngeal tube, was sufficient for the treatment of most cases. It was rarely necessary to use cocaine, except in very irritable throats at the beginning of the treatment. With the head well thrown back and under the guidance of the eye, the application was made, care being taken to avoid touching the epiglottis. The remedies employed should be soothing as well as

mildly stimulating and antiseptic. He favored the use of menthol, olive oil, benzoinol, guaiacol, eucalyptol, camphor, and beechwood creosote. He had found the treatment exceedingly beneficial in the early stages of pulmonary tuberculosis.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 24, 1898.

ARTHUR M. JACOBUS, M.D., PRESIDENT.

Practical Hints in the Examination of the Blood.—DR. HENRY HEIMAN read a paper with this title. Speaking of the examination of the blood for the malarial plasmodium, he said that the microscopist must carefully distinguish between nucleated cells, degenerated corpuscles, and fungi developing in the methylene blue. The special distinguishing feature was the presence of the characteristic brown pigment. The best stain for parasites in the blood such as the malarial plasmodium was the double methylene blue and eosin. Incidentally he mentioned that the malaria observed in New York City and its immediate vicinity was nearly always of the tertian type. Blood smears might be fixed at once by formalin, or the fixing process might be postponed for some time. As a rule, the plasmodia were found in the red cells, stained a light bluish color, and had a form varying with the stage of the disease. In chronic malarial poisoning the plasmodium was rarely found.

Anæmia.—No matter what the cause of the anæmia, the principal microscopical change was a diminution in the number of the red cells, the decrease in number being in proportion to the severity of the anæmia. Crenated corpuscles or vacuoles might be found in the cell's substance, due to the decomposition of the red cells or to an absence of the hæmoglobin. There might be a decrease in the number of the red cells, and yet a normal percentage of hæmoglobin.

Chlorosis.—In chlorosis the leucocytes were seldom increased in number. The red cells did not take up the stain as well as usual, owing to the absence of hæmoglobin.

Pernicious Anæmia.—In pernicious anæmia there was an unusual paleness, even in the fresh blood drawn from the finger. The number of red cells was enormously decreased, and the cells were of many shapes and sizes. The differential diagnosis between primary and secondary pernicious anæmia was made by noting that in the primary form there were more nucleated red cells.

Hodgkin's Disease.—In this disease microscopical examination of the blood furnished positive results. Three varieties of leukæmia were usually described, viz., (1) the splenic, (2) the myelogenic, and (3) the lymphatic. This classification could not be substantiated by the microscopical findings, yet it was a satisfactory division from a clinical standpoint. There was a decrease in the number of the red cells and in the quantity of hæmoglobin, and the plaques were supposed to be increased in number. There was a marked increase of the lymphocytes, especially in the lymphatic type of the disease, and found also unds in this form a few myelocytes and nucleated red ceils.

At the conclusion of the paper, Dr. Heiman exhibited his hæmatocrit and various other instruments used in examining the blood.

A Study of the Plasmodium of Malaria.—DR. RICHARD STEIN read this paper. He said that the examination of the blood for the plasmodium enabled the clinician to distinguish between the two great classes of malarial fevers—the benign and the malignant. The blood of the spleen, liver, and bone marrow became melanotic in certain very severe forms of malaria, because the blood had become loaded with the malarial plasmodia. Different types of fevers might be produced by the direct inoculation of animals with blood containing the various parasites. The period of incubation had been determined to be thirteen days in the tertian, ten days in the quartan, and about three days in the malignant malarial fevers. At first Laveran's discovery had not been accepted, and his descriptions had been said to be due to artefacts. It was not until the International Congress in Berlin, in 1890, that European scientists in general had been convinced of the truth and value of this discovery.

Benign Malarial Fevers.—The benign class of malarial fevers included the tertian, the double tertian, and the quartan—the tertian and double tertian being produced by one and the same parasite, and the quartan by a distinct parasite. The malignant or æstivo-autumnal fevers were the quotidian and the tertian. The tertian was caused by a distinct species of parasite. The development of the tertian fever was strictly parallel to that of the tertian parasite. Its period of development was exactly forty-eight hours. It began as an unpigmented spot in the red blood corpuscle, and this soon exhibited active movements. At an early stage, dark pigment in the form of granules and rods appeared, being formed from the hæmoglobin. When the parasite was nearly full grown it might be seen to undergo segmentation and to form from sixteen to thirty young spores. Meanwhile the hæmoglobin had disappeared. Finally the disorganized corpuscle was ruptured and the spores were set free. These, in turn, attached themselves to other red corpuscles, and a new cycle in development was inaugurated. The intensity of the fever depended upon the number of the organisms in the blood, yet it must be remembered that several generations of organisms were found in the blood at one time. If two generations matured in twenty-four hours, a daily paroxysm occurred, giving rise to a double tertian. The quartan parasite required seventy-two hours, and hence a chill took place every fourth day.

Malaria in New York City.—Dr. Stein said that he had examined a large number of cases of malaria in this city, and had in almost every instance found the tertian parasite. It was true, however, that many of these patients had infected themselves in the outlying districts now comprised in Greater New York. Two cases of tertian were reported which had developed in New York City, one of them terminating fatally.

Intermittent Pneumonia.—Sometimes malaria occurred under the type of an intermittent pneumonia. This affection had been described by French, German, and Italian observers as occurring in epidemics of malaria. It was impossible at present to explain the pathological basis of this affection; all that we could say was that there was such a thing as primary intermittent pneumonia, due to malarial infection.

Typhoid Fever and Malaria.—That typhoid fever might be complicated by malaria had often been suspected, but it had only recently been substantiated by blood examinations. Dr. Stein reported two such cases, and stated that Osler and W. Gilman Thompson had reported several others. Much confusion existed as to the so-called "typho-malarial fever," certain severe forms of malignant malaria sometimes being described under this name. Assistant Surgeon Woodward first used this term, and intended to designate by it a special disease first observed by him in the war of the rebellion. It is also known as "Chickahominy fever." This disease was associated with peculiar ulcerations in the small and large intestine. In the war between Russia and Turkey, in 1877, more than one-fifth of the total number of cases in the military hospi-

tals had been said to be typho-malarial fever. The existence of a separate disease of this kind was a question as yet by no means definitely settled.

Malarial Element.—By the term "malarial element" was meant a condition in which malaria was present in the system as a residue of a previous infection, producing no other symptoms than perhaps a slight malaise. If some other affection supervened or the patient underwent some violent strain, the dormant malaria suddenly became active. The importance of a blood examination in such cases could not be too strongly emphasized.

Æstivo-Autumnal or Malignant Fevers.—These were characterized by the readiness with which the initial quotidian or tertian type merged into a continuous fever, and by the tendency to relapse. Its malignant character was manifested by a severe toxæmia, which sometimes terminated in coma and death, occasionally with subnormal temperature. Three forms of parasites were described—the unpigmented quotidian, the pigmented quotidian, and the malignant tertian. All of these were smaller than those found in the other variety. The parasite, as it developed, either underwent sporulation, or else took the form of a spherical or crescent-shaped body. The examination of the blood in children was of special importance, because of the difficulty of determining the size of the spleen in them. Epidemic influenza in children, moreover, very closely simulated malaria, the fever running a long course and showing distinct intermissions. It was not uncommon to find only fifty per cent. of the normal hæmoglobin after a malarial fever of three weeks' duration, and the red cells of the blood correspondingly reduced in number. During the paroxysm there was a considerable decrease in the number of leucocytes, though it was not so marked as in typhoid fever.

Value of the Blood Examination.—Dr. Stein declared that the examination of the blood in doubtful cases of malaria was now considered to be one of the most valuable additions to our diagnostic methods, but its value was always only relative. All authors agreed that the plasmodium could be detected in the large majority of cases, especially shortly before and during the paroxysm, on the other hand, they were equally positive that there was a small number of typical cases in which repeated and painstaking examinations elicited only negative results.

Technique.—He was of the opinion that every practitioner could and should make these blood examinations. Three things were necessary: a thin, smooth blood "spread," a faultless method of fixing the blood, and a clean staining fluid. A drop of blood was placed on a thin cover glass and a second glass on this; then the two glasses were slid rapidly apart, at the same time that they were gently pressed together. In this way a smooth "spread" was obtained. To fix the blood the glass might be placed on a copper plate, one end of which was heated. The staining was done with a weak alcoholic solution of eosin and a concentrated watery solution of methylene blue. If the coloring fluids were not too recently prepared, the staining might be accomplished almost instantaneously. The preparation was washed in water after each stain. If the cover glass was allowed to float on the solution or was in it for a long time, impurities could not be avoided.

Splenic Enlargement and Malaria in Children.—Dr. Henry Koplik said that he had met with cases of simple uncomplicated malaria in children, occurring strictly within the limits of New York City. His cases had not been complicated with pneumonia, nor had they been of the malignant type. Enlargement of the spleen in children was of little diagnostic value without a corroborative examination of the blood. Quite severe cases of tertian malaria occurred in children in whom there was no enlargement of the spleen, and many cases in which the spleen was enlarged were not malarial. The easiest method of preparing the blood, he thought, was that of Ehrlich, which had been already described by Dr. Stein. It was an extremely convenient method for bedside investigation, as the blood could be preserved indefinitely, if kept dry.

Dr. Richard Van Santvoord said that it was quite possible to carry around a fresh drop of blood for two or three hours, and still have it fit for microscopical examination. He had sometimes been disappointed at not finding the plasmodium in fresh blood from individuals who had contracted malaria in New York City.

Dr. James Ewing said that if an examination of the blood immediately after the first chill, and before quinine had been given, failed to disclose the plasmodium, he would feel quite sure that the case was not one of malaria. The feeling of distrust among clinicians regarding these examinations was due to a wrong point of view. The malarial organism was not found, for instance, in chronic malarial cachexia, or even in a first attack of tertian malaria after quinine had been given for some time. It was sometimes absent also in cases of æstivo-autumnal fever that had run a long course, but in the first attack, quinine not having been given and the attack being sharp and distinct, the organism could be found in sufficient numbers to make the examination easy.

Counting White Blood Cells.—Dr. Ewing said that for a number of years he had used with much satisfaction a method of counting the white blood cells, which had given him more accurate results than the method with acetic acid. The method required a single blood pipette, and was best conducted with a special chamber and a mechanical stage. The blood was diluted with one-per-cent. salt solution. The acetic-acid method left a large amount of detritus, the leucocytes were very apt to cling together and appear in clumps in the field of the microscope, and especially when the total number of leucocytes was low the dilution with salt solution gave more uniform distribution of the leucocytes and more uniform results. He had found many inaccuracies in the use of even tested Fleischmann hæmoglobinometers.

Alcohol and Ether Fixation Preferable.—He had long since given up the method of heating the specimen of blood on a copper plate, preferring the fixation by alcohol and ether. This method was easily applied; all that was necessary was to drop the specimen into a wide-mouthed bottle, containing equal parts of strong alcohol and ether, and leave it there for from fifteen minutes to several hours. After this it might be kept indefinitely. In fixing the specimen by heat it would be found that if the heating were carelessly done the staining would not enter so easily and thoroughly as when prepared by alcohol and ether. Moreover, when a large number of specimens were taken and it was desired to keep them for any length of time, he had found that if they had been hardened by dry heat they were very apt to change after a time and refuse to stain with eosin, while taking up the methylene blue with avidity. This was not the case with the specimens hardened in alcohol and ether.

Typho-Malarial Fever a Misnomer.—Dr. M. Manges also objected to resorting to the old method of making blood smears with cover glasses and fixing them by heat; he greatly preferred the more modern method with formalin. It seemed to him unfortunate that Dr. Stein should have spoken of a subject that had been thought almost dead—*i.e.*, typho-malarial. In his opinion this name should be dropped absolutely, and we should speak of typhoid fever and malaria, rather than of malarial typhoid.

Thionin Stain.—He had found a very simple method of staining the plasmodium of malaria to be that

with thionin—a single stain presenting a very vivid picture of the plasmodium. The specimen could be stained and mounted in two or three minutes, so that it seemed to be an ideal clinical method.

Dr. Heiman replied that the only objection to the thionin was that in the later stages of the malarial organism, when pigment was present, it was sometimes obscured by the dark color of the thionin.

Dr. Stein said that the more practice one had in examining for the malarial plasmodium, the fewer "negative" cases one would meet with. He had had, however, several typical cases in which it had been impossible to arrive at any definite conclusion regarding the diagnosis by an examination of the blood, even during the first attack, yet clinically these cases had been unquestionably malaria. There could be no doubt that there were certain cases of typical malaria in which the plasmodium could not be found in the peripheral circulation. Regarding the cases of malaria and typhoid fever, he said that Dr. Osler had described several cases of typhoid fever with malarial exacerbations, and had stated in this hall that these were not frequent. Dr. Stein said that a reference to the literature would show that many authors had demonstrated the occurrence of malaria with typhoid fever.

Committee on Midwifery Legislation. — The report of this committee was received, but action was postponed until the special meeting for the consideration of this subject, to be held on January 31st.

Special Meeting, January 31, 1898.

Nathan E. Brill, M.D., Vice-President, in the Chair.

Discussion on Proposed Legislation against Midwives.—This was the special order of business for this meeting.

Midwives Have No Legal Status.—Dr. E. H. Grandin opened the discussion by the assertion that none but legally qualified physicians should practise midwifery, because, according to the medical-practice act, only those were legally qualified practitioners of medicine who had passed the regents' examination. Last year, he said, the legislature had refused to pass the opticians' bill, on the ground that opticians were not properly qualified to fit glasses, having no knowledge of medicine. Yet there had never lived in this city a midwife who possessed the requisite qualifications. There was now before the legislature a bill from Montgomery County, having for its object the proper training and licensing of midwives to practise in that county. The trouble was that, while it might be possible to train a person to sit by the bedside and watch ordinary labors, such a person could not be taught to recognize many complications or the time to call in a medical practitioner. Moreover, it was difficult to conceive how even a properly trained person could carry on modern antiseptic midwifery and at the same time be expected to scrub the floors. It was the plain duty of the County Medical Society to tell the community why educated midwives could not exist. If, after it had performed this duty, the legislators did not respond, then the onus of mortality and morbidity would rest upon their shoulders. It was safe to say that fully thirty-three and one-third per cent. of the diseases peculiar to women were due to defective midwifery. As this society had figured as the pioneer in securing the higher medical education, of which it was now so justly proud, it should not take a retrograde step and license midwives.

Resolution.—Dr. Grandin then moved the adoption of the following resolution: "That in the opinion of the Medical Society of the County of New York it is contrary to the good of the community that midwives should be tolerated, even though partly educated, and that, therefore, it is the sense of this society that its committee should be instructed to draft a bill for introduction into the legislature, wiping out the midwives at present existing without legal status, and forbidding under penalty any but legally qualified physicians from practising any branch of medicine." The motion was seconded and the discussion continued.

Deal Liberally with Midwives now in Practice.—Dr. H. J. Garrigues said that he agreed with the preceding speaker that midwives were an unmitigated evil; at the same time he did not quite agree with that part of the resolution which spoke only of their abolition. It should be remembered that we had to deal with a numerous class, and that many of those composing it had considerable influence. It must also be remembered that the community was against us, because of its bringing up in regard to this custom. For these reasons there would be little hope of successful legislation if great care was not taken in formulating a bill. He had consulted an able lawyer, and had been told that it would not be possible to get through the legislature a bill which imposed an examination upon those already in practice. We should be satisfied, therefore, with getting rid of the midwives gradually. Even some in the medical profession were still of the opinion that midwives had a right to exist, and were useful members of the community. He would, therefore, favor the drafting of a bill which would be very liberal to the midwives now in practice.

Educate Them.—Dr. Mary Putnam Jacobi said that it should be remembered that there was still such a thing as a normal confinement. It was to meet this contingency that midwives were supposed to exist. The bill now before the legislature imposed all the restrictions now imposed in European countries upon midwives. Matthews Duncan's statistics showed that after a first natural confinement the chances of complications fell very rapidly in succeeding confinements, up to the ninth. It might be desirable to limit the activity of midwives to the period between the first and ninth confinements. The result of a legislative attempt at the abolition of midwives would be that these same poor women who now employed them would be driven to depend upon nurses or ordinary woman helpers. The proposed measure seemed to her not only impracticable, but unjust and unnecessary. When this matter came up before the London Obstetrical Society, the president of that body stated that midwives must be either improved or abolished. The English decided to adopt the first alternative—they improved them. Just one hundred years ago midwives had been abolished by law in this country, and certainly for upward of fifty years they were not to be found in certain sections of the country. It was but just and right that our midwives should receive the thorough training given them in Europe.

Physicians to Blame for the Present Condition.—Dr. M. B. Feeney did not believe that a bill to abolish midwives could be passed through the legislature. The present condition of affairs was largely the fault of the physicians themselves, who refused to attend these poor people. An effort should be made to better equip the midwives for their work.

A Great Sacrifice of Human Life.—Dr. David P. Austin thought it would be found that the main portion of the arguments presented for the abolition of midwives was unanswerable. Unless one voted to sanction the sacrifice of many human lives, one could not sanction the practices common and current in this city. The following were cases in point: He had been called by a brother practitioner to attend a confinement—a case of arm presentation that had been

under the care of a midwife for sixteen hours. The arm had been denuded of skin by her efforts at delivery. When the physicians were summoned, the midwife hastily left the patient's house, pulled down the sign from her own door, and disappeared. Dr. Anderson said that on his arrival the woman was found to be almost pulseless. Version was very rapidly performed, but in five minutes the mother died—two lives were thus destroyed. In another case of arm presentation, attended by a midwife at the beginning, he had barely succeeded by strenuous efforts in saving the mother's life, but the child was sacrificed. In still another case he had been hastily summoned to a house, twenty-four hours after a delivery by a midwife. Finding the child had been hastily dressed just before his arrival, and that it was very white, he suspected hemorrhage, and on removing the clothes, found the funis spurting blood almost as if it had not been tied at all. The hemorrhage was at once controlled, but the child died in half an hour. This happened under the care of a midwife who had been educated in Germany, and who had a large practice. He could easily cite twenty such illustrative cases. In his opinion the midwives could not be educated; the only treatment adequate to the present situation was a strong effort to rid the city of New York of this nuisance. In country districts the law could be very materially modified.

Education Not Coercion.—Dr. Seneca D. Powell said that the present age was a period of education, not of coercion. A recent case in point was to be found in the workings of the medical-practice act. Since the establishment of this law and of the State board of medical examiners, over eight hundred candidates had been refused license to practise medicine. The necessary restrictions on midwives could be imposed by the medical profession; then its duty would have been performed.

Our Obstetric Teaching at Fault.—Dr. J. J. E. Maher expressed the opinion that the reason for the existence of midwives was to be found in the manner in which obstetrics had been taught in the medical schools—it was wholly empirical as regarded normal labors. It was for this reason that women so often said, "Any one can deliver a woman."

To License Means to Perpetuate Midwives.—Dr. Robert A. Murray said that there were supposed to be about thirty-seven hundred midwives in this city. He asked: "Does it seem reasonable that a woman with a training of six months should be as well qualified as a physician after four years of education, not only in one branch, but in all the branches of medicine and surgery?" It had been argued in favor of the midwife that she could afford to go for a smaller fee, as she went from house to house attending to a number of cases at a time. It was just here that there was a great danger—that of carrying infection from place to place. If the sentimental objection was offered that the livelihood of these poor women would be taken away if midwives were abolished, the answer was that there was nothing to prevent suitably educated women from entering the medical schools and qualifying as medical practitioners. A very important point to remember was that if midwives were licensed we were likely to have them in perpetuity; on the other hand, a law could be passed which would prevent further additions to their ranks, and in this way they could be gradually abolished.

Dr. Julius Rosenberg said that a similar resolution had been adopted by this society about five years ago, after the reading of his paper. He had stated then, and would now repeat, that about thirty thousand confinements in this city were conducted by midwives, and that the mortality from stillbirths was eight per cent., whereas under proper medical supervision it was only about three per cent. This in itself seemed to him sufficient reason for the society again going on record as desiring to abolish midwives.

Dr. J. S. Peterson expressed himself as in favor of a law which would abolish all midwives who had not been in practice more than five or possibly ten years.

Dr. M. J. Lewi expressed the opinion that the local ordinance of the board of health requiring the registration of midwives was illegal, because in conflict with the provisions of the medical-practice act. The resolution as it now stood would therefore place the society in a ridiculous position before the legislature. The resolution should express the belief that midwives had no legal status, and call upon the guardians of the law to do their duty.

The County Society is Guardian of the Medical Laws.—Mr. Purrington, former counsel of the society, and at present chairman of the committee of the Society of Medical Jurisprudence having this special matter under consideration, was asked to express his views. He said that this question had been coming up before this society ever since 1808, when a certain woman endeavored to practise midwifery without the permission of this society. The society was the guardian of the medical laws.

An Interesting Legal Experience.—The speaker then stated that he had once endeavored to bring a civil action against a midwife in New York City, who had attempted to deliver a woman. It was claimed that she had attempted to deliver a child by pulling on the arm; that the child became impacted, and that Dr. Lusk had had to perform craniotomy. The case was clear. The woman was French, and it so happened that it pleased an inscrutable Providence to put five Frenchmen on that jury. The case had been clearly proved. In the course of conversation with the judge, a judge of the supreme court, while the jury was out, the judge had told Mr. Purrington that he personally believed in midwives, and that his wife was always attended in confinement by one. The verdict was in favor of the defendant, and inquiry afterward elicited the statement that the case of malpractice had been clearly made out, but the jury did not think that the defendant was guilty. The inference was clear, *i.e.*, the physicians in attendance were to blame.

Continuing, Mr. Purrington said that if the society contemplated abolishing midwives by a State law, it must count upon opposition from the counties of Erie and Niagara, where there was already in operation a local law. He did not believe that it was possible to pass a bill abolishing midwives, and an attempt at regulating their practice by legislation would at once confer upon them a legal status which they did not have elsewhere.

A vote was then taken on Dr. Grandin's resolution, and it was declared lost.

Hypodermic Treatment of Paralysis Agitans.—Moretti has treated several patients by hypodermic injections of atropine, and has obtained encouraging results. He begins with a quarter milligram and gradually increases to two milligrams twice daily. Gullhorn and Mendel prescribe duboisine in daily quantity of one or two cubic centimetres. Schmitt recommends hyoscyamine in dose of one cubic centimetre. Hyoscine is preferred by some practitioners. Hyoscine for injection:

℞ Hyoscine (hydrochlorate) . . . . . 0.05 cg.
Sterilized vehicle . . . . . q. s. for 100 c.c.
S. One cubic centimetre daily.

Picrotoxin for injection may be employed in the same way. These drugs should be handled with great care.—J. Mousnier, *Journal de Médecine de Paris*, June 27, 1897.

Therapeutic Hints.

Gargle for Follicular Tonsillitis.—

℞ Creosote (beechwood) ..... gtt. viij.
Tr. myrrh..... ℥ij.
Glycerin..... ℥ij.
Water ..... ℥iv.
M. S. Use as a gargle.

—Levy.

Sciatica.—

℞ Opii pulv..... gr. xv.
Ipecac. pulv..... gr. xv.
Sodii salicylatis..... gr. cx.
Fld. ext. cascar. sagrad ..... q.s.
M. et ft. pil. No. xx. S. One to three a day.

—Benjamin Ward Richardson.

General Tonic.—

℞ Strychninæ sulphatis..... gr. $\frac{1}{60}$.
Acidi phosphorici diluti ..... ♏v.
Ferri phosphatis..... gr. i.
Quininæ bisulphatis..... gr. i.
Glycerini ..... ℥ss.
Elix. aurantii .....q.s. ad ℥ss.
M. et ft. solutio. S. Take before each meal.

—Winslow Anderson.

Uterine Hemorrhage Depending upon the Presence of Fibroids.—

℞ Ergotinæ ..... gr. i.
Strychninæ nitratis ..... gr. $\frac{1}{60}$.
Hyoscyaminæ..... gr. $\frac{1}{100}$.
Aquæ dest..... q.s.
M. et ft. solutio. S. Use hypodermatically every fifteen minutes until four doses shall have been given, after which use four times daily.

—Winslow Anderson.

Measles.—To develop the eruption and allay incessant laryngeal cough:

℞ Syrup of hydriodic acid,
Dover's syrup,
Syrup of tolu.....āā ℥i.

The Dover's syrup is to be lessened for infants. During the eruptive stage and throughout a broncho-pneumonia:

℞ Pot. acet..... ℥ij.
Spiritus mindereri,
Aquæ camphor.....āā ℥iij.

Give a teaspoonful every hour to a child, and a tablespoonful to an adult, with plenty of water. In case of sepsis, diphtheria, or debility, add one drachm of the tincture of chloride of iron.—John A. Larraber, *Pediatrics*, October, 1897.

Atrophic Pharyngitis.—

℞ Pilocarpinæ muriatis..... gr. ij.
Aquæ,
Glycerini .....āā ℥i.
M. S. One drachm t.i.d.

—Sajous.

In Œdematous Thickening of the Lymphatic Tissue of the Nasopharynx and Tonsils.—

℞ Ichthyol..... ℥iij.
Aquæ dest..... ℥v.
M. S. Apply once daily, after cleansing the parts with some alkaline solution.

—Kyle.

Non-Irritating Lubricant for Catheters.—

℞ Saponis pulv..... ℥i.
Aquæ dest..... ℥iij.
Mucil. chrondri crispi..... ℥iij.
Formalin (40 per cent.)..... ♏x.
Thymol..... gr. v.
Ol. thymi..... ♏v.
Alcohol ..... ♏xv.

—Howland.

Intercostal Neuralgia.—

℞ Tr. gelsemii..... gtt. c.
Syr. simp..... ℥iss.
Aquæ dest..... ℥vi.
M. S. Two to three drachms twice or thrice daily.

Do not use this prescription if the heart is feeble.—Cheron.

Gastric Catarrh with Constipation.—

℞ Resorcin. puri..... gr. xxx.
Tr. rhei..... ℥iss.
Ess. menth. pip..... ℥i.
Sodii bicarb..... ℥ij.
Inf. rhei .....ad ℥vi.
M. S. One drachm every two hours.

—Burney Yeo.

Gastralgia.—

℞ Morphinæ hydrochlor..... gr. iij.
Cocainæ hydrochlor ..... gr. v.–viij.
Tr. belladonnæ..... ♏i.–ij.
Emuls. amygd. amaræ.....ad ℥i.
M. S. Ten to fifteen drops every hour.

—Ewald.

Cirrhosis of Liver.

℞ Pulv. rhei rad ..... ℥ij.
Ext. aloes ..... ℥ss.
Ext. colocynthidis ..... gr. vi.
Ext. rhei..... q.s.
M. et ft. pil. No. lx. S. Two to be taken twice daily.

—Bamberger.

Epilepsy.—

℞ Potassii bromidi..... ℥iss.
Beta naphthol..... ℥i.
Sodii salicylatis..... ℥ss.
M. et div. in partes tres. One part to be given thrice daily.

—Feré.

Acute Rheumatism in Children.—

℞ Sodii salicylatis ..... ℥iss.
Potassii iodidi ..... ℥ss.
Tr. aconiti ..... gtt. x.–xv.
Aquæ ..... ℥ij.
M. S. One drachm t.i.d.

Caillé.

Heart Stimulant in Catarrhal Pneumonia.—

℞ Camphoræ..... gr. iss.–iij.
Flor. benzoin..... gr. iij.
Theobromæ..... gr. vi.
M. S. Three or four times a day.

—Caillé.

To Abort Influenza.—Several moderate doses of calomel in succession at the onset or before the third day.—Freudenthal.

Fissure of Anus.—Cocainize and apply pure ichthyol for several days.—Cheron.

Fissure of Nipple.—Paint with compound tincture of benzoin or with ichthyol; or apply:

℞ Extracti krameriæ..... ʒi.
Olei amygdalæ..... ℥iss.
Olei theobromæ .....ad ℥i.

Chloroform in Obstetrics.—The following propositions may be advanced: 1. The most recent experimental study indicates that the evil effects of chloroform result from vasomotor paralysis, causing the accumulation of blood in the abdominal viscera especially, and bringing about partial or complete cessation of function in the nervous centres from acute anæmia. 2. Pregnancy increases vasomotor tension, and thereby renders the pregnant woman less liable to the injurious effects of chloroform. 3. In normal labor, the actual expulsion of the child may be safely rendered painless, dilatation of the birth canal furthered, and laceration diminished, by light and transient narcosis from chloroform. 4. In tetanus of the uterus, eclamptic convulsions, and maniacal labor, chloroform is to be preferred to ether, and is most useful. 5. Pro-

found narcosis from chloroform is seldom if ever necessary in obstetric practice, and, like this condition under ether, is attended with risk.—E. P. Davis, *Dunglison's College and Clinical Record*, September, 1897.

Chloasma.—

℞ Chloralis hydratis 10
Acidi carbolici,
Tincturæ iodi..... āā 5
M. S. Apply with a soft brush.

—*Centralblatt für gesammte Therapie.*

Uræmia.—Ether, two centimetres, every hour day and night, by injection, alternating every hour with a teaspoonful of the remedy by the mouth in sweetened water. If the injections are too painful, give a teaspoonful every half-hour. If necessary, larger amounts can be given. The diuretic effect of the remedy is too little appreciated in this condition.—Lemoine.

Singultus Hystericus.—Trional, one gram, in five powders. One powder every two hours.—Spirt.

Urticaria.—

℞ Menthol ..... 5 gm.
Chloroformi,
Ætheris sulphuric.,
Spiritus camphoræ ..... āā 15 gm.

For wash or spray, after which rice powder or zinc oxide can be sprinkled over the regions acted upon.—Gaucher.

Diabetes in Children.—

℞ Antipyrin..... ʒ iij.
Glycerin..... ʒ i.
Water..... ʒ viij.
M. S. One or two tablespoonfuls daily.

—Josias.

Hay Fever.—Spray of Carlsbad water, followed by douching of the nose with a twenty-per-cent. to thirty-per-cent. silver solution, and afterward applying:

℞ Menthol..... 3 gm.
Resorcin ..... 3 gm.
Spirtus vini diluti..... 14 gm.

—Müller.

Or for a nose wash:

℞ Sodii bisulphatis..... 1
Aquæ destillatæ..... 500

—*Gazette Hebdomadaire.*

In Diarrhœa of the Tuberculous.—

℞ Pulveris catechu..... 2.50 gm.
Syrupi rhatanhiæ..... 30 gm.
Tincturæ cinnamomi... ..... 10 gtt.
Vini rubri..... 90 gm.
M. S. To be taken in tablespoonful dose during the twenty-four hours.

—Bricemoret.

For Localized Itching.—

℞ Hydrargyri chloridi corrosivi..... 0.30–0.50 cgm.
Alcohol ..... 25 gm.
Chloroformi..... 5 gtt.
Aquæ chamomillæ destillatæ..... 25 gm.
Aquæ laurocerasi..... 50 gm.
M. S. Apply locally.

—Leistikow.

Hemorrhoids.—

℞ Balsami peruviani..... 1
Acidi borici (finely pulverized) 20
Vaselini 100

If vaseline proves irritating, as it does in some instances, substitute benzoated lard.—Championnière.

Scarlet Fever.—The nurse should not eat or drink in the same room with the patient, and before going to meals she should clean her hands and arms with green soap and sublimate solution, 1 to 1,000, and put on a clean, long, loose gown, which hangs outside of the sick-room. During the period of desquamation the patient should receive a daily bath of tepid water containing green soap.—Augustus Caillé.

Headache Dependent on Ovarian Disease.—

℞ Ammonii bromidi..... ʒ vi.
Extracti hydrastis fluidi..... ʒ ss.
Tinturæ gentianæ compositæ..... ʒ iss.
Aquæ ..... q.s. ad ʒ iv.
M. S. Dessertspoonful thrice daily.

—Sinkler.

Pertussis.—

℞ Phenocoll hydrochloride,
Antipyrin .....āā gr. viiss.
Potassium bromide..... gr. vi.
Syrup of bitter orange peel,
Orange-flower water..... āā q.s.
M. S. Divide into four doses and give all in twenty-four hours to a child of eight years.

—Guaita.

Tuberculous Osteitis in children, when accompanied by suppuration, is treated with guaiacol benzoate, in five-grain doses, given thrice daily.—Rugh.

Clavus.—To remove the corn, soaking with hot water or a poultice over night will soften the part and admit of its being dug or picked out with little pain. The corn plasters contain various softening agents, such as carbonate of potassium and acetic acid; most of them are probably harmless and often ineffectual.—L. Duncan Bulkley.

Or:

℞ Iodine..... gr. ij.
Flexible collodion..... ʒ iij.
Alcohol..... ʒ i.
Potassium iodide..... gr. ij.
M. S. Paint the corn every night.

—W. L. Wilson.

Favus of the Nails.—After pyrogallol ether spray, paint with:

℞ Pyrogallol..... 1.50 gm.
Beta naphthol..... 2 gm.
Hydrargyri præcipitati albi..... 1 gm.
Tincturæ guaiaci.....30 gm.
M. S. Fasten brush in the cork.

—Leistikow.

Epilepsy.—

℞ Adonis vernalis..... 1.30 gm.
Infuse in
Aquæ..... 180 gm.
And add:
Codeinæ..... 0.10 cgm.
Potassii bromidi..... 4 gm.
M. S. Five to seven dessertspoonfuls daily.

—Tekoutief.

Tuberculous Cystitis.—For a calming suppository:

℞ Extracti opii..... 0.01–0.02 cgm.
Extracti belladonnæ..... 0.01–0.02 cgm.
Olei theobromæ..... ..... 5 gm.

Or:

℞ Extracti gelsemii..... 0.10 cgm.
Extracti opii..... 0.02 cgm.
Iodoform..... 0.05 cgm.
Olei theobromæ..... 5 gm.

—Colin.

Epistaxis.—

℞ Benzoic acid,
Tannic acid,
Carbolic acid.....āā 1
Collodion..... 20
M. S. To be applied.

—Bouzier.

Lumbago.—

℞ Sol. ac. boric. sat..... Oi.
S. Half a glassful every four hours.

—W. E. Putnam.

Chyluria which had resisted all other measures in two instances was followed by recovery after ichthyol in pill form: from fifty centigrams to two grams being the daily amount consumed.—Moncorvo.

Treatment of Pertussis.—Pure air; daily change of room every three hours, so as to secure proper ventilation, the temperature of each room being the same (66° F. or 68° F. for infants under one year of age). Remove from the rooms all carpets, hangings, and upholstered furniture. Vessels for reception of vomit should contain one-per-cent. sublimate or five-per-cent. carbolic. In infants below one year of age quinine should not be given, because of its bad effects upon the digestive apparatus. Antipyrin gives the best results. It is indispensable that the patient be free from albuminuria before giving it. To those less than one year of age from three to five centigrams may be given twice a day, and to those between one and two years from ten to fifteen centigrams: above this age as many decigrams as the child is years of age. At times good results are obtained by giving:

℞ Ammonii bromidi..... 0.10–0.20 cgm.
Extracti belladonnæ..... 0.005 mgm.
Two or three times a day.

—Wertheimer.

Sea Water by Intravenous Injection.—Hallion (*Soc. de Biol.*, December 4, 1897) has verified Quintori's experiments, which show that diluted sea water is well tolerated by the organism. Indeed, it seems to be better borne than other saline solutions. It may be injected more rapidly or at a rate of 1.5 gm. a minute for each kilogram of the subject's weight. The urine shows a greater density than with other saline solutions, and after forty-eight hours returns to normal. The bad effects of large quantities may thus, it would seem, be overcome by employing sea water.

Correspondence.

MODERN NOVELISTS AND MEDICAL SUBJECTS.

To the Editor of the Medical Record.

Sir: In the editorial on the "Modern Novelist and Medical Subjects" which appeared in the Medical Record of January 22d, it seems to me that scant justice is done to the immortal Dickens, when authors are advised, if distrustful of their medical knowledge, to do like him and touch upon such matters vaguely. Is it possible that the writer has forgotten, for he certainly must have read, Dickens' wonderful description of the development of pulmonary tuberculosis in the person of Smike in "Nicholas Nickleby"? Surely a picture so vivid, so true, must free the writer from the accusation of vagueness, and prove, if proof were needed, that the master hand that created for literature a Pickwick, a Weller, a Quilp, and the somnolent Fat Boy, to say nothing of Sairey Gamp and Betsey Prig, was quite capable when he wished to picture with pathological accuracy the ravages of disease. It was not the custom of Dickens to label his characters like the specimens in an anatomical museum, but none the less do we find in his pages types of mental and physical degeneracy whose delineation called for a wider knowledge than the mere description of the symptoms of disease, so easily obtained from encyclopedias. By all means let modern authors when writing of disease seek to know a little bit of their subject; but let us rather say that in so doing they will be following in the footsteps of Dickens, not by vague, but by accurate and vivid description.

S. S. Jones, M.D.

A NOVELIST ON MATERNAL IMPRESSIONS.

To the Editor of the Medical Record.

Sir: I read with much amusement your editorial in a recent number of the Medical Record on the "Modern Novelist and Medical Subjects." Perhaps the most delicious "display of ignorance" appears in Madame Sarah Grand's latest novel, "The Beth Book." (I have not the book at my elbow, so I cannot copy the scene word for word, as I should like to.)

The book opens with the mother of Beth engaged at her needlework, wishing she could afford the luxury of a fire, a good novel, instead of having to sit shivering in a cold room and go on with the week's mending, while her back aches and her head spins. Often in later years she would look back on that afternoon of cold and of intellectual hunger, and think what a difference it would have made in Beth's character had she (the mother) sat before a fire and read an interesting novel. In a few hours the labor pains begin and Beth is born.

An original contribution to the misty study of maternal impressions! A. N. M.

PHYSICIANS ON HOSPITAL BOARDS.

To the Editor of the Medical Record.

Sir: In your issue of January 22, 1898, appears the original article by Dr. A. P. Gerster on hospital management. I am in accord with most of the statements therein contained, but wish to correct an error of statement as regards to the management of private corporations. The author says: "None of our private hospitals admit any medical man to their boards of directors, except the St. Luke's and the German Hospitals." The Manhattan Eye and Ear Hospital, with thirty-five directors, has fifteen physicians. This was one of the first hospitals so to organize.

The New York Post-Graduate Hospital, with ten directors, has eight physicians on its board; in fact its charter requires that of twelve directors seven must be physicians in active practice.

I might mention other boards of directors in which the medical staffs are represented.

W. Oliver Moore, M.D.

New York, January 22, 1898.

ANÆSTHESIA BY THE SCHLEICH METHOD.

To the Editor of the Medical Record.

Sir: I have been very much interested in the various articles on the new anæsthetic, the Schleich solution, and have tried it a few times, adopting the suggestion of Dr. Willy Meyer, as found in the Medical Record of January 8th, of using oiled silk to prevent the too free evaporation of the solution.

I had the same experience probably that Dr. Meyer had, viz., the solution of the oiled silk by the chloroform in the mixture, disfiguring the mask and making it very unpleasant to handle. I then sought for something that was light, dense enough to keep the vapor below, insoluble in the mixture, and easy to handle.

I found it in the lead of tea chests. I took my ordinary Esmarch inhaler, laid a piece of good linen over it, and over that a piece of tea lead of the same size, with a round hole cut out of the centre, an inch in diameter. The linen and lead, being cut one-half inch wider than the two measurements of the mask, fold over and under, beneath the mask, and the pliability and weight of the lead hold them both to their place.

A trial shows that sufficient of the solution evaporates under the lead to secure profound anæsthesia in from five to ten minutes, with the use of one to three ounces of the solution.

Only one of our Omaha cases has shown cyanosis,

and in one case only has recourse been had to chloroform. Respiration has been remarkably free from embarrassment in all cases.

R. M. STONE, M.D.

OMAHA, NEB.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 29, 1898:

	Cases.	Deaths.
Tuberculosis	186	107
Typhoid fever	6	2
Scarlet fever	179	20
Small-pox	1	0
Measles	381	17
Diphtheria	170	18
Laryngeal diphtheria (croup)	7	0
Chicken-pox	54	0
Cerebro-spinal meningitis	0	2
Pertussis	8	0
Parotiditis	2	0
Erysipelas	2	0

Of Enormous Momentum.—A writer in the *Medical Brief* begins an essay in the following words: "Among the many persistent and rapidly prostrating diseases, I consider acute gastritis one of enormous momentum, for I have seen it bring about sorrow and gloom in only a short time."

A Suggestion made recently by the MEDICAL RECORD that the authorities of this city secure an invitation from the Louisiana leper settlement for New York's small colony to visit it, has been acted upon and overtures leading up to something of the kind have been made, it is said, by the health board. It would seem highly desirable, since the federal government will not do the proper thing by these outcasts, that private enterprise should take a hand and remove the stigma from this great city and from this great republic.

To Control the Wet Nurse.—Since Urnikoff has demonstrated (*l'Obstétrique*) that ammonia added to human milk causes a dark red color, varying with the amount of reagent (one drop of a ten-per-cent. solution added to five cubic centimetres of milk causing a violet hue), and that the longer the milk has been flowing the more intense is the reaction, we are in a position scientifically to verify a nurse's statements as to the length of time since her confinement.

Physician Cyclists in Germany.—In certain cities the doctor who rides a wheel wears a metallic badge having a red cross upon a white enamel background. This serves the same purpose as the fire badge worn by American newspaper reporters, or what the French call a *coupé file*. It might be that some such device, if adopted here, would save many from arrest for scorching or being caught out late without a light, or at least might save them the indignity of having their professional explanation questioned.

Kerosene Poisoning.—Kerosene oil is a frequently employed domestic remedy for the destruction of head lice in children; it is also given to horses in large quantities at times for the relief of colic. Instances of poisoning by swallowing the oil by mistake have recently been reported. In most cases strangulation would seem to be produced oftener than subsequent more serious effects. At any rate it seems to act well in animals, and human beings have taken considerable quantities without ill effects.

The Dispensary Bill.—The following is the bill introduced by Mr. Sullivan and now before the committee of public health of the New York senate:

"An act to amend the State charities law, relating to the licensing and regulation of dispensaries by the State board of charities.

"The people of the State of New York, represented in senate and assembly, do enact as follows:

"Section 1. Article one of chapter five hundred and forty-six of the laws of eighteen hundred and ninety-six, entitled 'An act relating to State charities, constituting chapter twenty-six of the general laws,' is hereby amended by inserting at the end thereof the following sections:

"§ 19. What is a dispensary.—For the purposes of this act, a dispensary is declared to be any person, corporation, institution, society, association or agent, whose purpose it is, either independently or in connection with any other purpose, to furnish, at any place or places, to persons non-resident therein, either gratuitously or for a compensation determined without reference to the value of the thing furnished, medical or surgical advice or treatment, medicine or apparatus; provided, however, that the moneys used by and for the purposes of said dispensary, shall be derived wholly, or in part, from trust funds, public moneys, or sources other than the individuals constituting said dispensary and the persons actually engaged in the distribution of charities of said dispensary.

"§ 20. Licensing of dispensaries by State board of charities.—A license may be issued by the State board of charities to a dispensary as provided in this section. An application in writing for such license shall be made to such board in the form and manner prescribed by it. There shall be attached to such application, a statement verified by the oath of the applicant, containing such facts as the board may require. If, in the judgment of such board, the statement filed and other evidence submitted in relation to such application, indicate that the operations of such dispensary will be for the public benefit, a license shall be issued to the dispensary applying therefor. The form of such license shall be prescribed by the board. A dispensary shall not enter upon the execution, or continue the prosecution of its purpose unless licensed by the State board of charities as provided herein.

"§ 21. Rules and regulations.—The State board of charities may make rules and regulations and alter or amend the same, in accordance with which all dispensaries shall furnish and applicants obtain medical or surgical relief, advice or treatment, medicine or apparatus. But such rules and regulations shall not, in any case, specify the particular school of medicine in accordance with which a dispensary shall manage or conduct its work, or determine the kind of medical or surgical treatment to be provided by any dispensary.

"§ 22. Revocation of licenses.—The State board of charities or any of its members may, at any and all times, visit and inspect licensed dispensaries. They may examine all matters in relation to such dispensaries and ascertain how far they are conducted in compliance with this law and the rules and regulations of the board. After due notice to a dispensary and opportunity for it to be heard, the board may, if public interest demands and for just and reasonable cause, revoke a license, by an order signed and attested by the president and secretary of the board. Such order shall state the reason for revoking such license and shall take effect within such time after the service thereof upon the dispensary as the board shall determine.

"§ 23. Drug store or tenement house not to be used by dispensary; unlawful display of signs.—After the taking effect of this act, no dispensary shall make use of any place commonly known as a drug store, or any

place or building defined by law or by an ordinance of a board of health as a tenement house; nor after such time shall any person, corporation, institution, society, association, or agent thereof, except a duly licensed dispensary, display, or cause to be displayed, a sign or any other thing which could directly, or by suggestion, indicate the existence of the equivalent, in purpose and effect, of a dispensary.

"§ 2. Any person who violates any of the provisions of this act, or any of the rules and regulations made and published under the authority of this act, shall be guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not less than ten dollars, and not more than two hundred and fifty dollars.

"§ 3. This act shall take effect October first, eighteen hundred and ninety-eight."

Milk Adulteration.—Water containing seventy-five grams of cane sugar per litre shows the same mark on the lactodensimeter as pure milk. If ten cubic centimetres of milk, suspected of being adulterated in this way, has fifty centigrams of molybdate of ammonium in powder added to it, and then ten cubic centimetres of hydrochloric acid diluted to one-tenth strength, and it is heated to about 80° C., it will turn to an intense blue if adulteration has been practised.—M. S. Cottar, *Lyon Méd.*, August 22, 1897.

Combining Fractions.—The nurse was ordered to administer one-sixtieth of a grain of strychnine. Finding only some tablets of one-fiftieth-grain strength, she asked to have ordered some one-tenth-grain tablets, so she could give one of each to make up the required dose of one-sixtieth.

A Bed Piano has been invented which straddles the sick-bed on elevated legs and has a keyboard so arranged at an angle that the reclining invalid with musical tendencies can put in his or her time to pleasant advantage.

Guinea-Worm Disease (Filaria Medinensis).—Among the native passengers and deckhands on that one ship, I saw seven cases of guinea-worm, and three others after landing at Batanga. The natives catch and wind around a match or piece of bamboo the portion of the worm projecting, and each day draw out a section by traction. In each of the ten cases I have seen, the worm was located in either the foot or the ankle. One worm when extracted measured three feet and four inches long, the diameter being approximately one-tenth of an inch.—Dr. A. L. Bennett, in a letter to the editor of the *Colorado Medical Journal*, December, 1897.

Intussusception.—Dr. Edward Martin, of Philadelphia, in answer to eight hundred letters sent out by him, finds that intussusception is most common about the sixth month, and that after the fifth year it becomes comparatively rare until the fortieth or fiftieth year, when it again increases in frequency of occurrence, In the first year of life the ileo-cæcal form is more common than the combined form of all the others, the ileal invagination being exceedingly rare. The lower part of the ileum is the part usually involved.

The International Leprosy Conference.—The following are the general conclusions adopted at the close of the International Leprosy Conference held in Berlin in 1879. As might be expected, a considerable portion of the discussion related to the bacillus leprae, which the conference accepts as the virus of leprosy, and which for upward of twenty-five years has been known to the scientific world through the important discovery of Hansen and the able investigations of Neisser. The conditions under which the bacillus grows and develops are still unknown, as well as is the way of its invasion of the human system; but from the discussions of the conference it seems probable that a unanimity of opinion will soon prevail in reference to its modes of subsequent dissemination within the human body. Very interesting observations were brought forward in connection with the elimination of the bacilli in large numbers by means of the skin and the nasal and buccal mucous membranes of lepers; it is desired that such observations be confirmed where opportunities occur. The question is of very great importance to those who are intrusted with the care of the public health, as leprosy is now acknowledged to be a contagious disease. Every leper is a danger to his surroundings, the danger varying with the nature and extent of his relations therewith, and also with the sanitary conditions under which he lives. Although among the lower classes every leper is especially dangerous to his family and fellow-workers, cases of leprosy frequently appear in the higher social circles. The theory of heredity of leprosy is now further shown to have lost ground, in comparison with the at present generally accepted theory of its contagiousness. The treatment of leprosy has had only palliative results up to the present time. Serum treatment has so far been unsuccessful. In view of the virtual incurability of leprosy and the serious and detrimental effects which its existence in a community causes, and considering the good results which have followed the adoption of legal measures of isolation in Norway, the leprosy conference, as a logical issue of the theory that the disease is contagious, has adopted the following resolution proposed by Dr. Hansen and amended by Dr. Besnier: 1. In such countries where leprosy forms foci or has a great extension, we have in isolation the best means of preventing the spread of the disease. 2. The system of obligatory notification, of observation, and isolation, as carried out in Norway, is recommended to all nations with local self-government and a sufficient number of health officers. 3. It should be left to the legal authorities after consultation with the medical authorities to take such measures as are applicable to the special social conditions of the districts. The secretaries of the conference were Phin. S. Abraham, London; E. Dubois Havenith, Brussels; Ed. Arning, Hamburg; J. J. Kinyoun, Washington; A. von Bergmann, Riga; G. Thibierge, Paris; and Edv. Ehlers, Copenhagen, general secretary.

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague, have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended January 29, 1898:

Small-Pox—United States.

		Cases.	Deaths.
Alabama, Bessemer	January 9th to 26th	29	
Birmingham	January 9th to 26th	78	
Talladega	January 9th to 26th	41	
Other points in Jefferson Co.	January 9th to 26th	25	
Georgia, Atlanta	January 20th to 26th	12	1

Small-Pox—Foreign.

China, Hong Kong	November 29th to December 4th.	1	1
Cuba, Cardenas	January 9th to 15th	..	1
Cienfugos	January 2d to 16th	..	8
Havana	January 14th to 20th	..	2
Sagua la Grande	January 9th to 15th	.. 35	5
England, Sunderland	December 16th to January 8th	1	
Japan, Miyagi Ken	December 17th to 27th	2	3
Saitama Ken	December 17th to 27th	1	
Yehime Ken	December 17th to 27th	2	1

AN EPIDEMIC OF DIPHTHERIA; DEMONSTRATING, IN A MARKED DEGREE, ITS CONTAGIOUS NATURE, AND THE VALUE OF IMMUNIZATION.

BY JANE L. BERRY, M.D.,

NEW YORK.

THE town of St. Johnsbury, Vt., has been for some time the scene of an epidemic of diphtheria, which in many respects presents features of unusual interest. The town, of from seven to eight thousand inhabitants, is the most important in northeastern Vermont. It is beautifully situated at the junction of the Moose, Passumpsic, and Sleepers rivers, in a hilly, picturesque region, about twenty-five miles west of the White Mountains. There is an altitude of seven hundred feet above the sea at the river level, the hills rising abruptly from eight to nine hundred feet higher. Malaria is entirely unknown.

The isolated position of the town, which is surrounded on all sides for many miles by a thinly settled area of country, has probably accounted for its comparative immunity in the past from contagious diseases. During the three years previous to January, 1897, no cases of diphtheria were reported to the health officer in St. Johnsbury. As no bacteriological examinations were made, it is of course possible that some of the cases of sore throat which occurred from time to time may have been due to the presence of the diphtheria bacillus, but no cases were encountered which could clinically be diagnosed as diphtheria. From the end of January until the beginning of December, 1897, eighty-four cases of diphtheria were reported to the health board. Owing to the fact that many cases were not recognized, being diagnosed as tonsillitis or membranous croup, it is probable that these figures give but a small idea of the real extent of the epidemic.

As will be seen from the subjoined notes, there were but a few cases in each month from January until the beginning of November. With the exception of the first few cases the history of infection can be clearly traced in almost every instance, and it is probable that had strict methods of quarantining been used from the beginning it might have been possible to stamp out the disease some time ago; but unfortunately in many instances no quarantine whatever was enforced, owing to the fact that a few of the oldest and most influential of the physicians persistently refused throughout to admit the existence of diphtheria or the necessity for isolating the patients. By the majority of the physicians the true nature of the disease was recognized from the outset, and every effort was made by the health officer and those in sympathy with him to check its course. Antitoxin was very generally used, and, whenever possible, patients were quarantined. The disease continued to spread notwithstanding, and during the three weeks following November 1st there were forty cases of diphtheria reported. Up to this time no bacteriological examinations had been made, but it was now decided to employ a physician to make cultures from the throats and examine for the presence of the Klebs-Loeffler bacillus, and through Dr. William H. Park, of the New York health department, the writer went to St. Johnsbury for this purpose. During a stay of two weeks examinations were made of one hundred and eighteen cultures, and Klebs-Loeffler bacilli were found present in thirty-seven individuals. In as far as was possible a history was obtained of ninety cases, notes of which are here given.

Fairbanks Village is a section of the town centring about the extensive factories of the Fairbanks Standard Scale Company, which carries on the principal industry of the place. Paddock's Village and Summerville are small hamlets lying at the opposite extremity of the town, and Railroad Street is the main business street of the community.

CASE I.—The first case diagnosed as diphtheria occurred in Fairbanks Village. A boy of ten years was taken sick January 19, 1897, with a clinically well-marked case of diphtheria of moderate severity. Antitoxin not used. Recovery.

The source of infection was not traced, and though the boy attended school for one day after illness began there was no apparent spread of the disease from this case.

CASE II.—March 3d. Paddock's Village. Girl of thirteen years in H—s family. Case well marked, moderately severe. Antitoxin not used. Recovery. Source of disease not traced.

CASE III.—March 16th. Paddock's Village. Child of four years in Swedish family. Severe onset. Tonsils and uvula covered with membrane. Temperature, 103° F. Considerable prostration. Antitoxin, 1,000 units, injected. Twelve hours later marked improvement, temperature and pulse normal, and membrane coming off rapidly. Quick recovery.

An elder brother had undoubtedly had the disease first, without medical treatment. Parents said he "blew out pieces of white skin" from the nose during his illness. This child went to the same school as children of H—s family.

CASE IV.—March 18th. Paddock's Village. Second case in H—s family, child of ten years. Considerable membrane on throat. Symptoms quite severe. Antitoxin, 1,000 units, injected, with same marked effect as in Case III. Recovery.

CASE V.—March 28th. Paddock's Village. Third case in H—s family. Child, age not given. Membrane present in throat. Antitoxin, 1,000 units. Recovery.

CASE VI.—Last of April. Paddock's Village. Fourth case in H—s family. Baby, age under one year. Laryngeal diphtheria. No antitoxin used. Died.

CASE VII.—Last of April. Paddock's Village. Mother in H—s family. Taken sick just before death of baby. Antitoxin, 1,000 units, injected. Recovery.

CASE VIII.—May 3d. Fairbank's Village. Girl of six years in T—— family. Related to H—s family of Paddock's Village. Aunt had nursed H—s children, returning to T—— household after death of H—s baby. Moderately severe. Antitoxin not used. Recovery.

Case IX.—June 28th. Fairbank's Village. Man in T—— family, aged thirty years. Antitoxin not used. Died.

Case X.—July 4th. Centre of town. Girl of ten years in B—— family, ragpickers. Child severely attacked. When first seen, temperature, 106 F.; much prostration, and thick, firm membrane covering tonsils and uvula, and extending to pharynx and hard palate. Antitoxin, 1,000 units, given at 3 P.M.: repeated at 11 P.M. Next morning child found sitting up at breakfast with family: temperature normal, membrane coming off. Recovery.

Case XI.—July 7th. Centre. Second case in B—— family. Younger girl. Temperature, 106° F. Membrane extensive, covering tonsils and uvula. Antitoxin, 1,000 units. Recovery.

Cases XII., XIII.—August 26th. Centre. Boy of twelve years, and girl of sixteen years in L—— family. Disease in boy mild. In girl more severe, and followed by paralysis of muscles of deglutition. Antitoxin, 1,000 units, in each case. Recovery.

Cases XIV., XV., XVI., XVII.—September 2d. Centre. Four younger children in L—— family. Antitoxin, 1,000 units, given in each case. Recovery.

Case XVIII.—Paddock's Village. Child. Case diagnosed as "membranous croup" by physician in charge. Family not quarantined. No antitoxin used. Died.

Case XIX.—September 3d. Paddock's Village. A. T——, a boy of thirteen years. Lived near family last mentioned, and after death of child the toys it had used were sent to children of T—— family. On September 3d, A. T——, an anæmic, ill-nourished boy, woke up complaining of sore throat. When seen by physician, later on same day, membrane present on both tonsils; temperature, 101.5° F. Given calomel tablets and listerine gargle.

Next day, membrane about the same; child feeling much better: temperature below 100° F.

September 5th, boy found out of doors, with membrane spreading over palatine arches. House quarantined. Father refused to allow antitoxin treatment.

September 7th, membrane spreading over pharynx: continued to extend for four or five days, invading the nares and probably also the middle ear, the child complaining of intense earache, followed by rupture of the membrana tympani and discharge from the ear for several days. The membrane on the throat was of very tough, leathery consistence, and two weeks elapsed from the beginning of the attack before it entirely disappeared. Throat externally enormously swollen.

Considerable albumin was found in the urine from the fourth day of the illness. On the tenth day the amount of urine passed became very scanty, highly albuminous, and contained hyaline and epithelial casts. At the same time vomiting and diarrhœa began. Under active treatment these symptoms subsided, but albumin continued present in the urine during the entire illness.

There was marked cardiac depression from the beginning of the attack; the pulse was weak, irregular, and intermittent, with a steadily increasing anæmia.

Three weeks from the beginning of illness the boy got out of bed while alone, and was found unable to stand, owing to complete loss of power in the muscles of the right leg. This paralysis gradually lessened; in two days power seemed fairly well restored in the right leg, but at this time the left leg was paralyzed, loss of power continuing complete for twenty-four hours, then rapidly returning. The knee jerk disappeared from both limbs, and when examined, November 26th, was still entirely absent from the left knee, partially restored in the right. The boy's gait was still somewhat uncertain at this time.

During the latter part of October vision was found to be affected, diplopia existing for about two weeks. The child was treated at this time with electricity and massage. Strychnine and hypophosphites, with tonic wine, had been given internally from early in the illness.

Some time after release from the house, exact date not known, the following attack took place in the doctor's presence. While exerting himself slightly with arms raised, the boy suddenly gasped, staggered, and would have fallen had he not been caught. There were extreme pallor, nystagmus lasting a moment only, no twitching, and consciousness was not affected. In a few moments the attack had apparently passed off, but the boy complained that his hands "felt queer," and it was found that he had entirely lost the ability to grasp. The arms could be moved feebly, but there was complete motor paralysis in the muscles of the hands. In about an hour ability to use the hands began to return, and in a few hours seemed to be entirely restored. Reflexes not examined. Recovery, without development of further symptoms.

Case XX.—September 8th. Centre. Baby of J. H——. Lived opposite L—— family (Cases XII.–XVII.). Older sister had sore throat after playing with L—— children. Baby taken sick with symptoms of laryngeal diphtheria. Case diagnosed at first as "membranous croup," and no antitoxin administered until just before death. Child died in forty-eight hours from beginning of attack.

Cases XXI., XXII., XXIII.—Three cases in H–r–s family, near centre of town. Two children and mother. Illness lasted some time, and was followed by paralysis of palate in mother; paralysis still present at end of November. Patients were not quarantined, as the cases were diagnosed and treated as tonsillitis.

Case XXIV.—September 12th. Centre. Girl of twelve years in W—— family, living next door, to family last mentioned. Antitoxin, 1,000 units, given. Quick recovery.

Case XXV.—September 12th. Centre. Girl of fourteen years in G—— family, two doors from last case. Symptoms were so mild that antitoxin was not thought to be necessary, and none was given. Patient died two weeks later of acute nephritis.

Case XXVI.—September 15th. Near Railroad Street. Mrs. B——, membrane on tonsils and uvula. Marked cardiac depression. Antitoxin, 1,000 units, given. Recovery.

Cases XXVII., XXVIII., XXIX.—September 20th. Same neighborhood. Three children of Mrs. S——. Had played with H–r–s children (see Cases XXI., XXII., XXIII.). Mild cases. No record of treatment. Recovery.

Case XXX.—September 27th. Same neighborhood. Girl of seven years, living near H–r–s family just mentioned. Played with H–r–s children, and went to same school. Constitutional symptoms marked. Membrane present on throat and in nose, with marked fœtor. Antitoxin, 1,000 units, given. Marked improvement in twenty-four hours. Recovery.

Case XXXI.—September 27th. Paddock's Village. M. T——, aged ten years, sister of A. T—— (Case XIX.). This child, early in August, had been severely burned over the left hypochondriac region. The burn was very slow in healing, and about the time the brother's illness began skin grafts had been applied. September 27th, one week after the grafting, the child complained of pain in the burn, and on examination the surface was found to have become dark in color, as if bruised, and around the grafts a thin, gray, filmy membrane was forming. This membrane continued to spread until it had covered the entire surface of the burn, the portion around the grafts becoming tough and leathery in consistence. No constitutional symptoms developed until two days later. At

this time there was a rise of temperature to 102 F., the child complained of feeling sick, and patches of thick, creamy membrane appeared on both tonsils. The parents were now as desirous to have antitoxin given as they had formerly been opposed to its use, and 1,000 units was injected at 10 A.M. At 5 P.M. the temperature was normal and membrane on throat loosening at edges. The membrane on the wound persisted for five days. After its disappearance the child was released from quarantine. When seen, November 22d, the wound presented a sluggish, suppurating surface, from four to five inches in diameter. A culture made from the discharge at this time, seven weeks from onset of above attack, showed typical and numerous Klebs-Loeffler bacilli.

Case XXXII.—September 29th. Paddock's Village. Younger child in same family as above. Case mild. Nearly well when first seen by doctor. No antitoxin. Recovery.

Case XXXIII.—Centre. Fourth case in S—— family (see Cases XXVII., XXVIII., XXIX.). Mild. Antitoxin, 1,000 units, given. Recovery.

Case XXXIV.—October 10th. Paddock's Village. Boy of thirteen years, son of L. H—r, next door to H—s family. Rather mild. Antitoxin, 1,000 units, given. Recovery.

Case XXXV.—October 21st. Centre. Boy of thirteen years, lived around the corner from H—r—s family (see Cases XXI., XXII., XXIII.). Marked constitutional symptoms. Much membrane on tonsils. Antitoxin, 1,000 units, given very early in attack. Quick recovery. Partial paralysis of muscles of accommodation.

Case XXXVI.—October 21st. Centre. Mrs. C. C——. Case quite severe. Much membrane on tonsils and uvula, considerable prostration. Antitoxin, 1,000 units. Recovery.

Case XXXVII.—November 1st. Boy of fifteen years, student at academy. Antitoxin, 1,000 units. Recovery.

Cases XXXVIII., XXXIX.—November 3d. Centre. Boy of six years, and woman of thirty years, in family of Mrs. C. C—— (Case XXXVI.). Boy's case very light. Woman quite sick, membrane quite extensive. Antitoxin, 1,000 units, in each case. Recovery.

Case XL.—November 4th. Paddock's Village. Girl of thirteen years in B—g family. Lived near A. T—— and M. T—— (see Cases XIX. and XXXI.). Mild case. Antitoxin, 1,000 units. Recovery.

Cases XLI., XLII., XLIII.—November 5th. Paddock's Village. Mother and two children in D—— family. Children went to Paddock's Village school. Cases all rather light. Antitoxin given in each. Recovery.

Case XLIV.—Summerville. V. B——, adult, brother of Mrs. C. C—— (Case XXXVI.). Throat sore one day, with slight exudate. The house was quarantined, but no other cases developed in family, and this one was so light that considerable doubt was felt as to its diphtheritic nature, especially as the patient stated that he had not come in contact with his sister. The fact is not without interest that this man worked every day in a factory, next to the father of A. T—— and M. T ——.

Case XLV.—November 6th. Railroad Street. Girl of six years in J—— family. Treated for "membranous croup." No antitoxin. Died.

Case XLVI.—November 7th. Railroad Street. Little girl in I—— family. Antitoxin, 1,000 units. Recovery.

Case XLVII.—November 7th. Railroad Street. Young woman in hotel. There had been three cases diagnosed as tonsillitis in the same house, ill some three weeks. Young woman's case mild. Antitoxin, 1,000 units. Recovery.

Case XLVIII.—November 7th. Baby in family of A. T—— and M. T——. Had been sick a week before physician was called. When first seen, the membrane had extended to larynx and the case was hopeless. Antitoxin, 1,500 units, injected, but child died a few hours later.

Case XLIX.—November 7th. Paddock's Village. Boy of eight years, living around corner from last case. Symptoms mild. Antitoxin, 1,000 units. Recovery.

Cases L., LI.—November 8th. Paddock's Village. Child of three years and mother in C—k family. Lived near last cases; children attended same school. Had both felt sick for two or three days, with sore throat for one day, when physician was called. Throat in each case deeply congested, with small patch of membrane on one tonsil. Mother: temperature, 101 F.; pulse, 110. Child: temperature, 102 F.; pulse, 120. Antitoxin, 1,000 units, given to child; none to mother, as case seemed mild. Twenty-four hours later child's throat showed a thin membrane covering both tonsils and extending to pharynx; temperature and pulse as before. Mother: temperature, 103 F.; pulse, 120; thick, white membrane covering both tonsils, palatal arches, and large patch on pharynx. Antitoxin, 1,500 units, now administered to mother, with grave doubts as to good result when given so late in attack. Following day child about the same. Mother: temperature, 102 F.; pulse, 120 and weak; entire pharynx as far down as it could be seen, both tonsils, and uvula covered by a thick, gray, firmly adherent membrane, which in places extended over hard palate halfway to front teeth. Could swallow only a small amount of liquid with much difficulty.

Next day, November 10th, child's throat clearing, all symptoms much improved. Mother: temperature, 99° F.; membrane loosening at edges, throat emitting very foul odor.

November 11th, throat clean in child; in mother membrane coming off in large strips. Permanganate and H_2O_2 used as local treatment. Membrane persisted till November 17th. Paralysis of palate developed in both cases—slight in child, complete and lasting for some time in mother.

Cultures taken November 23d, Klebs-Loeffler bacilli in both cases.

Case LII.—November 10th. Centre. C. C——, husband of Mrs. C. C—— (Case XXXVI.). Case quite severe. Membrane over both tonsils and uvula. Temperature, 102 F.; pulse weak and irregular. Antitoxin, 1,000 units, on second day of illness. General condition much improved in twenty-four hours. Membrane disappeared from throat in forty-eight hours. Recovery.

Case LIII.—November 10th. Paddock's Village. Baby in family of J. S——. Had broncho-pneumonia, temperature ranging to 105.5 F. On eighth day of pneumonia, after temperature had been gradually falling and all symptoms improving, there was a rise to 105° F., and the throat showed membrane on both tonsils. Antitoxin, 800 units, given. Temperature continued high, and two days later membrane had invaded nares. At the same time entero-colitis developed, lasting several days. Membrane remained on tonsils three days; laryngeal symptoms continued four days. Pieces of thick membrane were expectorated, and a small piece of tough, leathery membrane was passed from the bowels. Paralysis of muscles of deglutition developed one week after onset of attack, and continued till the end of November.

Cultures from the throat, November 23d, showed Klebs-Loeffler bacilli present.

Case LIV.—November 11th. Paddock's Village. Third case in C—k family (see Cases L., LI.). Girl of ten years. Membrane present on throat for seven days. Antitoxin, 1,000 units. Recovery.

Culture, November 23d, Klebs-Loeffler bacilli present.

Case LV.—November 11th. Centre. Child of three years at academy boarding-house. Severe case. Antitoxin, 1,000 units, injected twice. Membrane cleared up, but child died ten days later of acute nephritis.

A boy of seventeen years, student at the academy and boarding at this house, had had sore throat for three days preceding the baby's illness. This boy left for his home in Barnet, a neighboring town, just before the baby's seizure, and two weeks later a younger brother of this boy and also two other children in his neighborhood were attacked by diphtheria.

Case LVI.—November 11th. Paddock's Village. Trained nurse who had cared for B—g child (Case XL.). Case mild. Antitoxin, 1,000 units. Recovery.

Cases LVII., LVIII.—November 12th. Two boys at academy boarding-house. One case very light; the other moderately severe. Antitoxin, 1,000 units, given early in both cases. Recovery.

Case LIX.—November 12th. Summerville. B. J——, boy of seventeen years. Membrane on tonsils. Considerable cardiac depression. Antitoxin, 500 units, repeated in twelve hours. Recovery.

Culture, November 21st, Klebs-Loeffler bacilli present.

Case LX.—November 12th. Paddock's Village. Fourth case in C—k family (see Cases L., LI., LIV.). Boy of eight years. Patches of membrane on pharynx, tonsils, and soft palate. Considerable constitutional depression. Antitoxin, 1,000 units. Recovery.

Culture, November 23d, Klebs-Loeffler bacilli present.

Case LXI.—November 13th. Paddock's Village. School teacher. Case moderately severe. Antitoxin, 1,000 units. Recovery.

This school, at the beginning of the epidemic, consisted of twenty-six pupils. At this time the attendance was reduced to five, when, owing to the teacher's illness, the school was closed.

Case LXII.—November 13th. Near Railroad Street. A. B——, a boy of ten years, a son of Mrs. B—— (Case XXVI.). This boy took care of his mother during her illness, but developed no symptoms until four weeks later. Possibly infected at that time through washing done by his mother for the C—k family. Physician not called until illness had lasted from three to four days. Membrane then covering both tonsils; temperature, 102.5° F.; pulse weak and rapid. Membrane continued to extend over pillars and uvula during next forty-eight hours, at end of which time there was complete paralysis of the vocal cords. Strychnine had been given internally, and antitoxin, 1,000 units, was now injected. Twenty-four hours later temperature and pulse were normal, membrane becoming detached. Voice not regained until November 25th, the boy then beginning to articulate with difficulty.

Culture, November 19th, Klebs-Loeffler bacilli present.

Case LXIII.—Centre. Mrs. B—k. Does washing; probable infection from this source. No record of treatment. Recovery.

Case LXIV.—November 14th. Paddock's Village. R. S——, newborn child in family of J. S—— (see Case LIII.). This child was born three days before above case began. Remained in same room with sick child. One week after birth a gray membrane formed over the stump of the umbilical cord, which was surrounded by a dark red indurated area, about six inches in diameter. The membrane continued present for several days, leaving a moist suppurating surface when it disappeared. The child had no rise of temperature, and developed no constitutional symptoms. Antitoxin not given.

Culture from stump, November 23d, Klebs-Loeffler bacilli present.

Case LXV.—November 15th. Academy boarding-house. Boy of sixteen years. Light case. Antitoxin, 1,000 units. Recovery.

Case LXVI.—November 15th. Centre. Second case in family of Mrs. B—k (Case LXIII.). Treatment not stated. Recovery.

Case LXVII.—November 15th. Adult, engineer, living at academy boarding-house. Quite sick. Tonsils and uvula covered with membrane, and marked constitutional symptoms. Antitoxin, 1,000 units. Recovery.

Culture, November 18th, Klebs-Loeffler bacilli present.

Case LXVIII.—Summerville. Boy, H. U——. Lived near B. J—— (Case LIX.), and went to same school. Case quite severe. Membrane on tonsils and uvula, and considerable constitutional depression. Antitoxin, 1,000 units, injected, followed by rapid improvement. Recovery.

Culture, November 18th, Klebs-Loeffler bacilli present.

Case LXIX.—November 16th. Paddock's Village. J. S——, father of R. S—— (Case LXIV.). Attack began with chills, nausea, and cold sweats. Considerable cardiac depression. Very thick, leathery membrane covering left tonsil; also patch on right. Antitoxin, 1,000 units, given, followed in twenty-four hours by great improvement in all constitutional symptoms, but membrane persisted in throat for five days. Recovery.

Culture, November 23d, Klebs-Loeffler bacilli present.

Case LXX.—November 16th. Paddock's Village. C—k family. Fifth case. Girl of fourteen years. Case seemed so light that antitoxin was not given, but membrane persisted in throat for nine days, and then there was a slight paralysis of soft palate.

Culture, November 23d, Klebs-Loeffler bacilli present.

There were eight persons in this house when the disease began. One young man left immediately, and has not been attacked. Of those remaining in the house, the father and one child received immunizing doses of antitoxin, given November 8th—the father, 300 units; the child, 200 units. These were the only members of the family who escaped attack.

Case LXXI.—November 17th. Paddock's Village. H. S——, boy of four years, fourth case in family (see Cases LIII., LXIV., LXIX.). Early in morning uvula and both tonsils found to be covered with thick membrane, but no constitutional symptoms whatever, child appearing well and active; temperature and pulse normal. By night the temperature was 104.5° F.; pulse rapid; child prostrated. Antitoxin, 1,000 units, given. Next morning, temperature, 99° F.; child bright and playful, membrane coming off. Recovery.

Culture, November 18th, Klebs-Loeffler bacilli present.

Mrs. S——, mother of these children, had been confined but three days before the first child was attacked with diphtheria. She remained in close contact with the four cases, in unhygienic surroundings and without protective treatment, but, strange to say, escaped infection.

Case LXXII.—November 17th. Seventh case at academy boarding-house. Boy of eighteen or twenty years. Case mild. Antitoxin, 1,000 units. Recovery.

Culture, November 18th, Klebs-Loeffler bacilli present.

Immunizing doses of antitoxin, 500 units each, were now given to all in the household who had so far escaped infection. These numbered sixteen persons, ranging in age from fifteen to seventy years. No further cases of diphtheria have developed among them.

Cases LXXIII., LXXIV.—November 17th. Railroad Street. Two children in I—— family. One case quite severe. Antitoxin, 1,000 units, given in both. Recovery.

Culture from M. I——, November 27th, Klebs-Loeffler bacilli present.

Case LXXV.—November 17th. Fairbank's Village. M. G——, girl of thirteen years. Went to Union School; sat across the aisle from girl who went home sick with sore throat. M. G—— developed typical symptoms, considerable prostration; temperature, 103° F.; pulse, 120 and irregular; tonsils, uvula, and soft palate covered with membrane. Antitoxin, 1,000 units, given. Membrane continued to increase, and forty-eight hours later a second injection, same amount, was given, followed by great improvement. Considerable albuminuria for several days. Toxic symptoms in this case marked; heart action still weak. December 1st, recovery.

Culture, November 18th, Klebs-Loeffler bacilli present.

Case LXXVI.—November 21st. Railroad Street. R. S——, boy of twelve years. Case light. Antitoxin, 1,000 units, given early in attack. Recovery.

Culture, November 18th, Klebs-Loeffler bacilli present.

Case LXXVII.—Summerville. Mrs. U——, mother of H. U—— (Case LXVIII.). Case mild. Antitoxin, 1,000 units. Recovery.

Culture, November 23d, Klebs-Loeffler bacilli present.

Case LXXVIII.—W——, young adult. Recovery. No further details of case.

Culture, November 18th, Klebs-Loeffler bacilli present.

Case LXXIX.—November 22d. Paddock's Village. A. R——, boy of six or seven years. Considerable exudate and marked symptoms. Treatment not stated. Recovery.

Culture, November 22d, Klebs-Loeffler bacilli present.

Case LXXX.—November 22d. Paddock's Village. D. Y——, girl of eighteen years, niece of Mrs. R—— (see Case LXXIX.), living on floor below in same house. Moderate severity. Membrane on both tonsils. No notes of treatment. Recovery.

Culture, November 22d, Klebs-Loeffler bacilli present.

Case LXXXI.—November 23d. Centre. M. S——, young woman who lived with H–r s family (see Cases XXI., XXII., XXIII.). Quite sick; membrane extensive. Antitoxin, 1,000 units, given early, with marked effect. Recovery.

Culture, November 24th, Klebs-Loeffler bacilli present.

Case LXXXII.—November 24th. Paddock's Village. A. B——, boy of eight years. Tonsils enormously swollen, but very little exudate visible. Symptoms later indicated membrane in nares and nasopharynx. Antitoxin, 1,000 units. Recovery.

Culture, November 27th, Klebs-Loeffler bacilli present.

Case LXXXIII.—November 24th. Fairbank's Village. Mrs. G——, mother of M. G—— (Case LXXV.). Severe attack. Membrane on tonsils. Heart much affected. Albuminuria for several days. Antitoxin, 1,000 units. Recovery.

The other children in this family, a girl of fifteen and a boy of seven or eight, were given immunizing doses of antitoxin when the first child was taken ill. Both escaped attack.

Case LXXXIV.—November 29th. Waterford, five miles from St. Johnsbury. C. D——, boy of ten years. Both tonsils showed membrane and were considerably enlarged. Temperature, 100.5° F.; pulse, 140. Antitoxin, 1,000 units, injected. Next day membrane increased on tonsils; pulse still rapid and weak. A second injection of antitoxin, 1,000 units, given, followed by decided improvement. Recovery.

Culture, November 29th, Klebs-Loeffler bacilli present.

This boy lived in an isolated farmhouse, with healthy surroundings. On Thanksgiving day he had gone with his parents to a neighboring town, and stayed all night, sleeping with a boy who had "sore throat." Taken ill soon after return home. It has since been learned that M. T—— (Case XXXI.) had previously visited at that same house.

Cases LXXXV., LXXXVI.—December 1st. Paddock's Village. In family of J. S—— (see Cases LIII., LXIV., LXIX., LXXI.), L. M——, a young woman, and R. S——, boy about five years old. In these cases immunizing doses of antitoxin had been given, November 22d. The attack in each was very mild, constitutional symptoms almost absent, the throat showing slight membrane on the tonsils. Some doubt existed as to the nature of the boy's attack, as only doubtful bacilli could be found in the culture.

Culture, December 2d, L. M——, Klebs-Loeffler bacilli present.

Culture, December 2d, R. S——, doubtful bacilli only.

Case LXXXVII.—December 1st. Baby G——, mother and child boarded with Mrs. R—— (see Case LXXIX.). Baby severely attacked. Exudate on both tonsils; temperature, 103° F.; and considerable prostration. Antitoxin, 1,000 units, injected. Next day much improvement. Day following, throat clean but symptoms of broncho-pneumonia had developed in right lung, followed by same condition in left lung.

Child died two weeks later. Autopsy showed pneumonia and general miliary tuberculosis.

Culture, November 28th, Klebs-Loeffler bacilli present.

Case LXXXVIII.—December 2d. Mrs. G——, mother of above. Membrane on tonsils, accompanied by constitutional symptoms. Antitoxin, 1,000 units. Recovery.

Culture not obtained.

Case LXXXIX.—December 3d. E——, young woman. History not given.

Culture, December 3d, Klebs-Loeffler bacilli present.

Case XC.—Paddock's Village. Mrs. C——. Not reported. House not quarantined. The case was diagnosed as tonsillitis, and the patient was instructed not to allow a culture of the throat to be taken. Notwithstanding the mild symptoms and slight exudate in this case, the culture, which was finally obtained by the health officer, showed most typical and numerous Klebs-Loeffler bacilli, the virulence of which was conclusively proven by tests to be described later.

It has since been learned that the husband of this woman acted as janitor for the Paddock Village schoolhouse during her entire illness. Fortunately for the community, this school chanced to be one in which the majority of the pupils were protected from infection by a recent attack of diphtheria.

As might be expected, where the diphtheria germs were so widely distributed, they were several times found present in the normal throats of those in contact with the sick. In one instance diphtheria developed later.

One patient, under treatment for facial erysipelas,

was reported to the health officer by the attending physician, as a case of mild tonsillitis. A culture made from the throat showed unmistakable Klebs-Loeffler bacilli, whereupon the physician stated that no throat symptoms had ever been present in the case. As there were no means of ascertaining which of these statements was the correct one, the case was excluded from the above list, as were all others which were not known to have exhibited either local or constitutional symptoms.

Through the courtesy of the New York board of health, an offer was made to furnish, free of charge, sufficient serum to give immunizing doses to all the school children, as it was felt that this would furnish a valuable illustration of the protective value of such treatment. The offer was regarded with favor by the school principals, and circulars were distributed among the parents, explaining the proposed treatment and requesting their consent. A favorable response was received in two hundred and twenty-one cases, and with the kind assistance of some of the physicians the above number of children and young adults were inoculated during the last week in November, with from 200 to 300 units of antitoxin, according to age. A careful record was kept of inoculations and subsequent developments. A local erythema and urticarial blotches appeared on the arm inoculated in some, but there was no general eruption or constitutional disturbance in any case. The last report was received January 16th. Up to this time not a single case of diphtheria had appeared among the immunized children, although many cases had developed in the schools during the interval.

Cultures from the throats of several patients were forwarded to the laboratory of the New York health department, and through the kindness of Dr. A. W. Williams, of the health department, the following tests of virulence were made:

Number of Case.	Weight of Guinea-Pig in Grams.	Amount 48 Hour Broth Culture Injected, in c.c.	Result.
75.....	250	0.01	Died in seven days.
75.....	274	1	Died in two days.
90.....	240	0.01	Died in five days.
90.....	230	1	Died in two days.
71.....	230	0.01	No apparent effect.
71.....	200	1	Died in two days.
62.....	216	0.01	No apparent effect.
62.....	255	1	Died in two days.

This table shows that the cultures from Cases LXXV. and XC. possessed decided virulence. This is less marked in Cases LXXI. and LXII., but still sufficiently pronounced to kill guinea-pigs in doses of one cubic centimetre.

The history of the above series of cases affords a striking proof of the infectious nature of the diphtheria poison and of the necessity for a strict quarantine in even the mildest cases. It will be observed that several of the most severe cases were contracted from those of the mildest type.

That mildness of onset affords no reliable indication of the final result is shown by the history of those patients in whom a mild beginning was followed by the development of serious and fatal symptoms later.

The effect of antitoxin treatment in this epidemic was most pronounced, and the low mortality record was perhaps due as much to the very general use of this remedy early in the attack as to the fact that the prevailing type of the epidemic was of moderate severity.

In almost every instance when antitoxin was given in time there was a prompt effect upon all symptoms. In many cases beginning quite severely, the attack seemed to be completely aborted by one inoculation, convalescence beginning at once, and this effect was the more noticeable, as the one thousand units uniformly used was in many cases a small dose. An interesting contrast is afforded by the course of the disease in two children of the same family—the one treated with, the other without antitoxin (see Cases XIX., XXXI.).

The comparative results of treatment are best shown by the following table:

Cases.	Treatment.	Deaths.
68.....	Antitoxin.	4—less than 6 per cent.
14.....	No antitoxin.	5—over 35.5 per cent.
8.....	Not stated.	
Total 90.....	.....	9

Deaths.

Case.	Treatment.	Character of Disease.
6.....	No antitoxin.	Laryngeal diphtheria.
9.....	No antitoxin.	Not stated.
18.....	No antitoxin.	Laryngeal diphtheria.
20.....	Antitoxin about twelve hours before death.	Laryngeal diphtheria.
25.....	No antitoxin	Acute nephritis following diphtheria.
45.....	No antitoxin	Laryngeal diphtheria.
48.....	Antitoxin about twelve hours before death.	Laryngeal diphtheria.
55.....	Antitoxin second day..	Acute nephritis following diphtheria.
87.....	Antitoxin second day..	Pneumonia following diphtheria, and acute miliary tuberculosis.

The value of protective inoculations was also strikingly illustrated. In two cases disease subsequently developed (see Cases LXXXV., LXXXVI.), but in one the diphtheritic nature of the attack was not proven, as a careful examination failed to discover any but doubtful bacilli in the culture, while in both the modifying effect of the treatment was seen in the very mild form of attack compared with the cases which had gone before in the same house.

As showing the efficiency of the above treatment, reference is made to Cases LXX., LXXII., LXXXIII., especially the last, as well as to the two hundred and twenty-one school-children who have escaped attack after repeated subsequent exposure.

231 East Twelfth Street.

PRIMARY TREATMENT OF POST-PARTUM HEMORRHAGE.

By MARTIN W. CURRAN, M.D.,

NEW YORK.

In my experience there are few situations more startling and requiring such promptness of action on the part of the obstetrician as that of post-partum hemorrhage, and, while all authorities whom I have consulted agree on this point, unfortunately they are harmonious in little else. Considering the gravity of the subject, there is a painful uncertainty in the advice imparted and a ridiculous tendency toward multiplying resources, forgetting the fable of the fox and the cat, and also that such methods display an infallible sign of weakness and of doubt as to their entire trustworthiness.

What is this condition which creates such terrible alarm? In the interior of a muscular bag at the end of an open passage is a space from which blood is pouring through a multitude of small mouths, this space being similar to the broad nozzle of a garden hose pipe. Around and between all these little

mouths are muscular fibres, which, should they contract, would act as so many ligatures, tying each and every vessel which had been opened by the peeling off of the placenta; if the muscular fibres do not contract, the vessels remain open, and every pulsation of the heart drives more and more blood out through them, until the general circulation contains too little for the nourishment of the important nerve centres which govern the acts of respiration, and the patient dies. These fibres have not contracted for the simple reason that the muscular walls of the uterus have been doing a good day's work in expelling their contents, and their contractile force is temporarily exhausted. Various uteri, various amounts of force. Some are firm and strong and not easily exhausted. Others are weak and flabby, and by the time they have reached the end of the second stage they are tired, used up for the time, and require rest before they can do more; but the blood which should revivify is pouring away, and as it courses out of the body they, in common with all the other muscles of the frame, become progressively weaker and weaker, less and less likely to recover. Now if we have stored in our minds the teachings of our authorities, we shall be alive to our responsibilities, but shall have only a miserable confusion of impracticable and entirely worthless ideas regarding the treatment of this condition, in place of the absolute certainty which should exist that we are doing the one and only thing which will succeed if the case is not entirely hopeless. Lusk says:[1] "Unlike other grave complications of childbirth, post-partum hemorrhage is not an uncommon event. It may follow the simplest of labors, and, in case of an unprepared physician, it may carry his patient in a few moments to the brink of death. It is impossible to conceive a tragedy more terrible than this. Occurring, as the accident does, suddenly, without warning, in the period of joy that follows the birth of a living child, the sudden shifting of the scene becomes appalling. If the mother dies at such a time, the luckless attendant who stands at her bedside a nerveless spectator need never expect forgiveness." And this is no fanciful sketch. The patient is tossing about the bed, gasping for breath, deaf, crying for help—to be let alone—to be allowed to die. Which is the more to be pitied—the unfortunate patient or the demoralized practitioner, who is driven to try first one thing and then another, to be immediately replaced by something else, which as likely as not is the absolute opposite of the last measure in its method of action? "Do not waste precious time" is the one driving thought. If a response is not obtained in a minute or so from ergot,[2] give it up; try strychnine.[2] At the same time pass the hand into the uterus,[3] clear out clots and placental remains; put in a lump of ice;[4] inject hot water;[5] inject cold water;[6] inject perchloride of iron;[7] pour cold water from a height on to the abdomen, careless of the soused bed and pneumonia which will follow;[3] flick the abdomen with a wet towel;[8] irritate the interior of the uterus with the hand;[8] knead the outside of the uterus;[9] throw the uterus into position of strong anteflexion;[8] autotransfusion—forcing blood out of the extremities into the heart and brain by means of bandages;[8] a pockethandkerchief saturated with vinegar and carried into the uterine cavity[10] is strongly recommended by Penrose—let us hope he means an unused one; invert the uterus—Kocks; sulphuric ether hypodermically;[11] bimanual compression;[4] faradic current—a battery is always at hand on such occasions;[8] packing the uterine cavity with gauze;[12] removal of the uterus by supravaginal amputation if hemorrhage continues after tamponing[13] will rarely be tried, though advised by one authority; child to breast[8] as a reflex excito-motor, etc. All the multitudinous suggestions of every author under the sun will have been put into practice, and the physician can console himself when all is over with the barren but unavailing consideration that he left nothing untried.

The physician may, if on the scene early enough, be sufficiently fortunate to get such a tetanic grip for a sufficient time as to allow clots to form in the numerous vessels. These may hold when the inevitable relaxation returns, and then the patient will recover: but consider the inherent improbability of this, and the chances of such a result decrease rapidly with each succeeding minute in which it does not occur. Most of the measures advised depend on the slender hope that there exists some latent contractility in the muscular uterine wall, and that this can be called out in sufficient force by some form of stimulation and maintained for a sufficient time to admit of the reliable formation and adhesion of plugs in the open arterial and venous mouths; but we must not forget that when stimulated the muscular fibres may at first respond by a spasmodic effort, which becomes weaker and weaker as time goes on—the more they are stimulated, the greater is the eventual collapse. Two methods are universally commended, viz., tamponing the uterus and the injection of a solution of perchloride of iron. We shall discuss the probabilities of their success.

Tamponing at first sight seems very reasonable and likely to succeed, and no doubt it might but for two important reasons against its value as a primary and certain remedy. The uterus in these cases is not a rigid bag, always of the same size. (Playfair[14] has said that the puerperal uterus will hold two ball dresses! This being true, one need not be astonished at the quantity of gauze required.) The irritation of the packing will stimulate the uterus to contract for a few seconds, and when the packing is completed it will appear to fill the uterine cavity absolutely and to exert some pressure on the uterine walls; but soon these walls relax; they have the entire abdomen to dilate in; the pressure is gone, blood accumulates between the tampon and them, and the mischief is now the more dangerous in that it gives no sign of its continuance without. The second reason is that the plug or packing will be soaked with blood and become practically a huge clot in the uterine cavity, prolonging and exciting while otherwise masking the actual loss.

Jewett considers "the uterine tamponade the most effective measure for the control of severe post-partum hemorrhage, reserving it, however, for desperate cases."[15]

In support of the assertion that the treatment is neither certain nor safe, Fritsch has recorded that it is unphysiological, for the uterus cannot be completely contracted while the gauze is in it.[16]

"Dr. Polk has tried the method in the Bellevue Hospital, and has been favorably impressed with its efficacy."[17]

Wallace says: "Never tampon after delivery; you might as well hang the woman by the neck."[18]

Verrier says: "I shall mention tamponing after delivery only to advise its rejection. Among its dangers we may name that of transforming external into internal hemorrhage."[19]

Next comes the injection of the perchloride-of-iron solution. The *rationale* of its action is the formation of clots in the bleeding vessels, and by its semicaustic action the stimulation of the vessels themselves to retract and contract. The solution is thrown against the ends of the vessels. It is met by all the force—what there is of it—of the escaping blood, tending to wash it away from them. Unless the force used—most of which will be wasted on the yielding uterine wall—is sufficient to overcome this, it is difficult to see how any, at all events sufficient, can enter; and it is

to be remembered that many if not most of the vessels open obliquely on the uterine wall. So that at best it is but a haphazard method of proceeding.

Compare the obvious duty in this case with the parallel obvious duty in ordinary surgery. A man's leg is rapidly cut off by a circular saw. From a multitude of small mouths spurts the arterial blood. In a few moments, unless prevented, the amount of available blood in the body will sink below that necessary to keep going the most important nerve centres. What is to be done? Should the surgeon douche the wound with hot or ice-cold water, or pour styptics over its spouting surface, or set to work and methodically tie all these vessels from the raw surface? He would laugh at the question, because here the procedure has been settled once for all on scientific grounds, and he knows for certain the one thing he must do first. The success of all depends on this primary duty, which is to compress the main vessels at once, and not until all the oozing or spouting was secured in detail would he relax this pressure. Let us consider the condition of the patient at this time. The abdominal wall has been stretched to its utmost for many months over the enlarging uterus. Now the uterus is emptied of all resisting contents, and the walls fall limp and flaccid over the abdominal cavity. The muscles, which normally might prevent by their firm contraction, are now powerless, and many weeks must elapse before they are again capable of resisting the pressure of a hand placed upon them. In this condition it is the easiest thing in the world for the obstetrician's hand to find and compress any structure in the abdomen. The aorta is placed in front of the one resisting firm material left, the lumbar spine.

PLAN OF THE RELATION OF THE ABDOMINAL AORTA.[20]

Front.

Lesser omentum and stomach.
Branches of cœliac axis and solar plexus.
Splenic vein.
Pancreas.
Left renal vein.
Transverse duodenum.
Mesentery.
Aortic plexus.

Right Side.

Right crus of diaphragm.
Inferior vena cava.
Vena azygos major.
Thoracic duct.
Right semilunar ganglion.

Left Side.

Sympathetic nerve.
Left semilunar ganglion.

Behind.

Left lumbar veins.
Receptaculum chyli.
Thoracic duct.
Vertebral column.

Between the obstetrician's hand in front and the vertebræ behind the aorta can be absolutely shut: no more blood can pass and no more blood will be lost. What remains in the vessels below the occluding hand when the driving power of the heart is shut off tends to clot, especially at their open extremities; what blood remains in the circulation above is kept for the use of the all-important nerve centres, and as more and more blood comes in from the veins, especially of the lower extremities, for the vena cava is carefully avoided, this reserve increases and respiration and circulation in the most important parts are increasingly provided for, while all the time the tissues which require rest, the ultimate ligatures, the uterine muscular fibres, are obtaining and profiting by that rest and becoming more and more fit to do the work of which they are perfectly capable when once they have recovered their condition. When necessary time has elapsed and their contractility has returned, then and then only is the time for their stimulation. What would be thought of the surgeon who held the femoral artery for a minute and then let it go before the vessels were closed on the wound front, and what is to be thought of the advice given by some leading authorities?

Barnes says: "I have occasionally derived advantage from it, and look upon it as a momentary resource."[21]

Playfair thinks that "as a temporary expedient it should be borne in mind and adopted when necessary."[22]

Jewett considers it "very effectual as a temporary expedient."[23]

Lusk thinks that "compression of the aorta through the abdominal wall is capable of rendering temporary service."[24]

". . . should all these measures fail, try to compress the abdominal aorta" (Verrier).[25]

It is precisely this half-hearted advice, which has a dozen resources in stock and trusts none of them, which is to blame for the general muddleheadedness of mind and is bound to result from a consultation of authorities. If one thing does not succeed, try something else; but the patient should no longer be considered doomed, for whom the physician is bound to do everything, in order to cover his reputation at the inevitable inquest.

Macewen has "effectively controlled the abdominal aorta by throwing the weight of the body on the aorta through the closed right hand, placed a little to the left of the middle line, the knuckles of the index finger just touching the upper border of the umbilicus. With the left hand the arrest of the blood current is ascertained by feeling the femoral at the brim of the pelvis. Only enough weight to arrest the femoral pulse is required. If the patient vomits or coughs, the pressure must be increased, lest the hand be lifted from the aorta by the abdominal muscles."[26]

In order to compress the abdominal aorta, it is not necessary but rather injurious to move the patient from the ordinary dorsal position. With the patient lying, as she usually does, flat on the back, the obstetrician's hand is easily applied under her without even disturbing the coverings of the bed, and avoiding exposure, which is the *sine qua non* of all remedial measures. The ulnar surface of the closed left hand—the physician standing on the right-hand side of the patient—should be laid gently but firmly across the aorta, which should then be compressed against the spine, while the right hand should feel for and compress the uterus. The hands may be changed from time to time, but the compressing hand should never be lifted until the other is in position above or below it and has taken up control of the vessel. The time during which compression is needed will vary with every case, and must depend wholly upon the cessation of hemorrhage and on no other factor. It is convenient and always necessary to have an assistant at hand, who may relieve the tired muscles of the original attendant. Two points are of great importance. First, inasmuch as the solar, epigastric, and mesenteric plexuses lie over and around the aorta, pressure must be shifted upward or downward from time to time. The pressure on the aorta does not matter, but too long continued pressure on any one point of the sympathetic does. Secondly, when pressure is taken off ultimately it must be very gradually done. The uterus should be felt to be firmly contracted: the aortic pulse should be firm, strong, and fairly slow; and the effect of releasing the current should be most carefully watched. If there is the least return of flow, the uterine ligatures are not yet to be trusted and compression must be resumed. This, then, is the primary duty. Once done and persisted in from the earliest possible moment until the desired firm contraction has been obtained and can be manifestly relied upon, the patient is safe as far as any earthly means can make her; and, with the entire self-possession which perfect security gives, the physician can quietly and without needless hurry put into force the secondary measures which are to bring about the

secondary result—namely, the firm and lasting uterine contraction. All these secondary measures require an appreciable amount of time for their satisfactory action; moreover, they all act best on muscular fibre which is recovering or has recovered its contractility. In this alone is seen the fatal mistake of considering them of primary importance, and of wildly flying from one to the other, vainly seeking for a result which the inherent conditions present render impossible or at best extremely improbable. These secondary measures are hypodermic injections of ergotin, brandy by mouth or rectum, raising the foot of the bed, hot bottles around the trunk, wrapping the head in hot flannel, kneading gently the uterus with the disengaged hand, removal of any clots or placental débris—which, now that the main source of blood supply is shut off, can be done with far more safety, because with calmness and deliberation; and examination of the os, cervix, and perineum for tears, and their repair.

But it may be said that this advice is only theoretical, and that no cases are on record to prove it. I suspect that the method is more in use among practical men than one would suppose from a perusal of the literature on the subject. Practising autotransfusion as described for cerebral anæmia, when aortic pressure is an easier and better method; or using Monsell's solution as a styptic, with its danger of producing gangrenous endometritis and secondary infection, in preference to applying the hand to the aorta, may be in favor with the savants of the profession, but hardly with another human being endowed with a healthy perception of the fitness of things, and who by experience realizes that in every case, whether complicated by retained placental fragment, torn cervix, or any other condition, the one and only measure of primary importance in the treatment of post-partum hemorrhage is compression of the aorta.

Spasmodic Wryneck is often alleviated by the administration of large doses of fluid extract of conium, sixty drops in twenty-four hours, and by the hypodermic administration of atropine. The galvanic current applied to the side of the neck oftentimes gives relief, particularly if the condition be painful; massage is also of service.—Joseph Collins.

RELATIONS OF THE RECTUM AND GENITAL ORGANS IN DISEASE.

BY BYRON ROBINSON, L.S., M.D.,

PROFESSOR IN THE CHICAGO POST-GRADUATE SCHOOL OF GYNÆCOLOGY AND ABDOMINAL SURGERY; PROFESSOR OF GYNÆCOLOGY IN THE [illegible] MEDICAL COLLEGE AND THE ILLINOIS MEDICAL COLLEGE; GYNÆCOLOGIST TO THE WOMAN'S HOSPITAL; GYNÆCOLOGIST TO THE WOMAN'S [illegible] HOSPITAL, AND CONSULTANT TO THE MARY THOMPSON HOSPITAL FOR WOMEN AND CHILDREN, CHICAGO.

Many authors have marked the close relation between the rectum and female genitals in disease. It is most manifest when the nervous apparatus of either rectum or genitals is involved. This relation must be considered on both anatomical and pathological grounds. A brief view of the great elemental structures, the muscles, nerves, vessels, and of the pelvic organs in close proximity, will aid in making the subject clear. The advertisements of sanatoria and institutions for special treatment of the diseases of women and of the rectum impress me that gynæcology and proctology are closely related. Though the appropriating of the gynæcological field by the proctologist may be a commercial move, yet there is an anatomical and pathological base in the intimate relation of the rectum to the female genitals. However, self-protection of the proctologist is much involved, for to-day the general surgeon presents unlimited assumption in his claim that he is capable of diagnosing all diseases and of performing all special and general surgical operations. The commercial and general specialist, like the poor, will always be with us. The real specialist, whose duty and practice are entirely devoted to definite organs, is the only one who can speak with authority as to the relation of gynæcology and proctology.

First, the organs are in close proximity. The same germs, especially the gonococcus, if in the vagina, pass over the perineum and enter the rectum, and *vice versa*. It has been shown that women have more rectal strictures than men, and some five years ago I advocated that gonorrhœa was a cause of rectal strictures. Gonorrhœa induces strictures of the urethral mucosa. The gonococcus affects mucous membranes, whether it be in the rectum, urethra, endometrium, conjunctiva, or pharynx. In the lying or erect postures, vaginal discharges are sure to pass into and infect the rectum. The gonococcus induces long and persistent discharges from the uterus, urethra, and the vulvar glands (vulvo-vaginal and peri-urethral), which sooner or later infect the rectum. Hence the close proximity of the rectal and genital organs allows interchange of infectious processes. The abuse of the sexual instinct, incident to civilization, has led to the evolution and establishment of a vegetable germ, the gonococcus, which is coexistent with humanity, persistent in action, and especially pernicious in effect on the genitals, thus endangering the adjacent rectum to similar diseases as the genitals. The gonococcus is, no doubt, a product of civilization, as we do not find it in birds, mammals, or higher apes; from these animals the most perfect form of marriage originated, and man is but an imitator. The forces of civilization induce promiscuous sexual practice.

The pelvic muscles closely relate the rectum and genitals, especially through the levator ani. The levator ani holds in its grasp the rectum, and largely influences the movements of the genitals. Any considerable movement of the rectum includes similar movements of the vagina, and *vice versa*. Irritation in either canal reflexly induces muscular contraction in the other. An ulcer or a fissure in the rectum will not only induce vigorous contraction of the sphincters (levator ani and sphincter ani), but also contractions of the vaginal canal and vulva. The rectal part of the levator ani being irritated, the whole muscle is set in motion. In a distant city I recently saw a typical ex-

ample of this. A young woman, married six months, became so hyperæsthetic that marital relations were almost impossible. Besides the intense muscular contractions about the vagina, I found the rectal sphincters in a state of intense vigorous and continuous contraction, amounting almost to a muscular spasm. Here the genital irritation had been reflexly transmitted to the muscles of the rectal region.

An illustration of this influence of the muscles is found in the fact that a rectal or perineal operation will cause retention of the urine for several days. When either genitals or rectum are in a pathologic state, *e.g.*, on account of fissure, ulceration, or infection, the muscular trauma of the levator ani aids in spreading the infection by irritation and maintaining motion. Muscular trauma must become an admitted factor in the dissemination of disease, and the levator ani is second only to one muscle (the psoas) in its opportunity and close relation to the rectum and genitals in effecting the spread of frequently infected organs bound closely together by double fascial folds. When the levator ani moves, the rectum and vagina move also.

Any irritation in the rectum may induce the levator ani to force the infected contents of a Fallopian tube on the pelvic peritoneum, thus aiding to spread genital disease. To test the vigorous action of the levator ani, one needs only to place the finger in the vagina or rectum and request the patient to cough. The traumatic action of the levator ani then becomes apparent. The pyriformis plays but a small factor in genital and rectal relations. The psoas muscle, however, by its trauma, plays here a significant rôle. We must include in rectal diseases the sigmoid flexure. In some three hundred personally recorded adult autopsies, I found that the meso-sigmoid possessed peritoneal adhesions in over eighty per cent. of subjects, and in quite a number of cases the fimbriæ of the Fallopian tube were found adherent to the peritoneum in the region of the highest range of action of the psoas muscle. In such cases the Fallopian tube and the meso-sigmoid become diseased through the traumatic action of the psoas muscle inducing the migration of virulent microbes and their products. In the case of the Fallopian tube, the traumatic action of the psoas muscle induced the migration of infective germs from the tubal lumen on the peritoneal surface. In the case of the meso-sigmoid, the traumatic action of the psoas muscle on the sigmoid flexure at times when it contained virulent germs, induced the migration of the germs or their products through the gut wall into the peritoneal surface, producing a plastic peritonitis. Here the Fallopian tube and the meso-sigmoid became pathologic from the same cause, viz., muscular trauma by the psoas magnus. Similar disturbances are produced on the right side by the psoas. In fact, there can be but little doubt that appendicitis is frequently produced by the traumatic action of the psoas muscle. Autopsies demonstrate this over and over again. Of course, for the psoas muscle to exercise its most detrimental effect on the Fallopian tube and sigmoid by its traumatic action, they must be located within the longest range of muscular action of the psoas. Few will doubt the traumatic power of pelvic muscular activity in disseminating infective disease and aiding in distributing venous emboli. The vicious action of the dilatation and contraction of the muscular wall of the rectum in an infected Fallopian tube is easily demonstrated.

The intimate vascular relations of the rectum and genitals intensify their diseased relations. The pelvis is the most distinguished province of the body for large and numerous veins. The peculiar characteristics of the pelvic veins are (1) frequent anastomosis at acute or right angles, (2) large size, (3) large numbers, (4) some occur double, (5) some are valveless, and (6) the aggregation of veins into large plexuses.

In general, the veins of the pelvic walls are valved, anastomose at acute or right angles, are sometimes double, accompany like-named arteries, lying on either side of the arteries, and empty into the inferior vena cava. Before emptying into the common iliacs, the veins generally coalesce to form a single trunk. Of the veins of the pelvic walls, the only one of especial importance in our theme is the obturator vein, because this vein is closely connected with the veins of the external genitals and rectum. On the left side, as the obturator vein returns its blood, it passes through the left common iliac, and retards the flow of blood not only from the genitals, but also from the rectum, as the middle hemorrhoidal and inferior hemorrhoidal veins also empty into the left common iliac. All blood coming from the genitals and rectum on the left side is apt to be retarded by the pressure of the right common iliac artery on the left common iliac vein.

The veins of the pelvic viscera are characterized by being valveless, thick, net-like, anastomosing plexuses which surround the organs like a web. They also have an associated erectile apparatus. It is to the veins of the rectal and genital viscera we should direct our attention in the relation of rectal and genital disease. We must note the vast plexus pudendalis, which includes the blood from the erectile tissue of the external genitals and the inferior hemorrhoidal vein; also the vesical plexus which surrounds the bladder like a web and coalesces into a changing number of venous trunks, to empty into the internal iliac. The especially interesting plexus from the middle and inferior hemorrhoidal veins, which surrounds the rectum like a coarse, wide-meshed network, passes their blood current on through the internal iliac to the pudendal and vesical plexus, while the superior hemorrhoidal vein sends its blood stream to the liver by way of the valveless portal system.

The plexus uterinus, with its vast changes of volume during pregnancy and menstruation, empties partly into the ovarian and partly into the internal iliac. This plexus spreads itself out between the ligamenta lata, forming the plexus pampiniformis. The plexus vaginalis surrounds the vagina with such large and numerous anastomosing veins that some consider the vagina an erectile organ. The plexus stands in manifold connection with other pelvic plexuses, and finally empties into the internal iliac vein.

In regard to the valves of the ovarian veins, I have dissected perhaps twenty-five bodies and found valves nearly always at the ovarian orifices, but especially in the left vein. The pelvic plexuses are very compressible; they can be emptied partly or wholly, and again their vacuum can quickly assume a full condition. The pelvic veins stand in loose connective tissue. Any obstruction in the liver congests the veins of the pelvis, and especially those of the rectum, which rest in loose, lax, yielding connective tissue, so that they get less support for their walls from surrounding structures than others. Besides, the rectal veins suffer dilatation from force of gravity, because the portal vein possesses no valves. Whatever tends to congest either genital or rectal veins tends to congest both rectal and genital viscera. It may be observed that the more spiral or curved the pelvic veins, the more healthy they are. Straight, elongated, and dilated veins are pathologic. The varicose or dilated condition of the rectal veins exacerbates the congestion of the pelvic viscera, as the two lower hemorrhoidal veins empty themselves by way of the pelvic veins. The enormous number and extent of the pelvic veins strike all students of anatomy, and, if their large amount of venous blood be retarded or infected, congestion will be inevitable and the migration of germs or their products through the

thin-walled veins will be extensive. Venous thrombi are apt to arise in the pelvic veins, complicating circulation and endangering the transmission of emboli to the brain, lungs, or kidneys. The rectal and genital veins being sometimes branches of one and the same venous trunk, congestion or disturbance in one will be accompanied by disturbance in the other. Of course, all of the veins of the extensive vascular plexuses of the pelvis carry numerous sympathetic nerves in the connective tissue surrounding the vessel wall. This makes the genital and rectal system a delicately balanced and complicated apparatus.

The relation of the genitals and rectum in disease is most manifest through the nervous apparatus of the parts. The chief factor is reflex action, *i.e.*, the disturbance in distant organs by a local irritation. The nerves of the pelvis consist of (*a*) spinal and (*b*) sympathetic. In the spinal nerves, branches of the same nerve trunks and plexuses supply the genital, urinary, and rectal organs. The sacral plexus gives branches to the bladder, internal and external genitals, and rectum, *i.e.*, the third sacral sends a large branch to the bladder, the third and fourth sacral send large branches to the internal genitals, and the third and fourth sacral (the pudic) send large branches to the rectum and external genitals. The trunk of the pudic nerve may be represented by the forearm, while its branches may be represented by the fingers of the hand—the little finger representing the large vesical nerve; the ring finger, the perineal nerve; the middle finger, the hemorrhoidal nerve; the index finger, the vulval nerve; and the thumb, the nerve to the clitoris. Therefore the genitals and rectum are bound together by very close and intimate connection by the spinal nerves. The spinal nerves hold the muscles of the pelvis in delicate balanced tension. The spinal nerves are those which manifest quick and acute pain.

The sympathetic nerves, much more extensive than the spinal, supplying the rectum and genitals, pass to them in large strands or by way of the respective blood-vessels. The internal genitals are supplied by the ovarian and hypogastric plexuses, while the rectum is supplied by the inferior mesenteric plexus—all three plexuses being branches from the great abdominal brain. However, the hypogastric plexus which passes to the uterus is controlled or modified in its rhythm by the utero-cervical ganglion (pelvic brain). The inferior mesenteric plexus passing to the rectum is controlled or modified in its rhythm by the inferior mesenteric ganglion. The ganglion which by connection with the ovarian plexus intervenes to modify or control the rhythm of the ovary is not fully known. There are a large ganglion at the origin of the ovarian artery and several smaller adjacent ones. It is much plainer and more manifest that the sympathetic system of nerves holds the genitals and rectum in a firmer and even more delicate balance than do the spinal. In short, the rectum and genitals are supplied by branches of the same ganglion—the abdominal brain—and to the abdominal brain we must look for the great disturbing reflexes which arise in disease of either rectum or genitals.

It is in reflex action from one viscus to another that we find the clinical manifestations. The removal of the result of reflex irritation is one of the chief functions of the gynæcologist or proctologist. The majority of neurologists appear to claim that a neuron acts only in the confines of the cerebro-spinal axis. Neurologists claim that no deep-seated disease is caused by reflex irritation, nor can it be cured by removing reflex or peripheral irritation. To me the most sensible view is that a neuron will act within its own sphere just as well in the abdominal brain as in the cerebro-spinal axis.

For the sake of argument, we will admit that deep-seated pathology is not due to reflex irritation nor is it cured by removal of peripheral or reflex irritation. But gynæcologic patients suffer less frequently from deep-seated disease than from superficial reflex irritation. They suffer from slight irritation in the stomach, slight headache, and backache, due to pelvic irritation.

The triumvirate of local disturbances in women is back, head, and stomach, and all pain here may be due to reflex irritation from pelvic visceral disease. Dr. Dana has written an article on the "Passing of the Reflexes." The reflexes may be passing, but they will never pass while humanity is afflicted with peripheral irritation and while the greatest amount of suffering is caused by reflected pain rather than by deep-seated disease.

The object of a neuron, a nerve cell, is to resent irritation whenever and wherever it comes, and this constitutes "reflex" disturbance of one organ, inducing disturbances in a distant organ.

Diseased genitals, as every practical gynæcologist knows, generally produce, by reflex irritation, pain in the back, head, and stomach. Irritation in the rectum long continued will produce similar disturbances. Thus it is observed that cerebro-spinal nerves, the pudic, hold in distinct and delicate balance the external genitals and rectum. Disturbance in one will affect the other. Now, whether peripheral irritation originates in the genitals or in the rectum, the continual action of reflexes will unbalance the whole visceral system, and the patient will gradually suffer from indigestion, non-assimilation, anæmia, and finally neurosis.

The close relation between the genitals and the rectum may be observed by the clinical fact that operations on the rectum often cause retention of urine. When pelvic cellulitis exists, which is generally subsequent to peritonitis, the vessels and nerves which pass through the pelvic floor are surrounded by perilymphatic spaces, and the distribution of infection is thus enhanced by muscular action. The perilymphatics can also carry the infection from rectum to genitals, and *vice versa*, on the veins, arteries, or nerves which perforate the various pelvic partitions. Rectal diseases may be gradually extended by the lymphatics into the great field of subperitoneal tissue involving the genitals. How frequently does genital suppuration perforate the rectum, inducing distressing and persistent rectal disease! The diseased relations of the genitals and rectum are enhanced by the intimate and close connections established by means of the lymphatics. The arteries, veins, and nerves are surrounded by greater or less sized lymph sheaths, which easily disseminate infection throughout the pelvis by muscular trauma or activity.

The neuro-vascular tracts surrounded by the perilymphatic sheath, like the perivascular lymph sheaths of the turtle, perforate the various partitions and are liable to carry slowly or rapidly infectious processes to the various pelvic tissues, from genitals to rectum, and *vice versa*. The physiologic or excessive action of the pelvic muscles aids the lymphatic channels to distribute infection.

The veins of the lower rectum and some of those of the genitals are apt to become varicose and dilated, and thus influence the circulation in either region.

The tendency of the veins to dilate, to become varicose (to form hemorrhoids), is partially explained by the fact that the rectum and genitals are depleted by two venous systems, both with no or imperfect valves; especially, the portal system not only has no valves, but has rapid variations in the congestions and depletions with unfavorable conditions as to specific gravity and position.

Again, the veins of both rectum and genitals are

detrimentally affected by violent respiratory efforts, particularly by coughing. One can observe by the eye vast dilatation and filling of the rectal and genital veins followed by depletion during short intervals of violent respiratory efforts.

Not only do the rectal veins form a close meshwork about the lower rectum, favoring congestions and depletions, but the arteries of the last four or five inches of the bowel penetrate the muscularis of the gut wall at different levels, course parallel to the bowel wall, and form intimate arterial anastomosis as they approach the anus. Hence we have in the rectum a double meshwork of anastomosis, both of arteries and of veins, and a vast meshwork of closely anastomosed veins in the genitals—all favoring diseased relations between rectum and genitals.

Rapid congestions and depletions of veins (and of arteries) in any tissue favor disease, which is enhanced by muscular trauma and the dissemination of infection.

The intimate relation of the anus and neck of the bladder is maintained chiefly by the fourth sacral nerve, which supplies the neck of the bladder and then passes to supply the sphincter and levator ani muscles. The pelvic viscera, skin, perineum, and muscles are all kept in intimate association by the second, third, and fourth sacral spinal nerves, and their circulation is held in delicate balance by the pelvic sympathetic. Disturbance in any one part of this complicated yet perfect nerve apparatus will tend to unbalance the remainder.

Conclusions.—1. The intimate and close relation of the rectum and genitals in disease may be frequently observed by the gynæcologist and the rectal specialist.

2. It is due to the close proximity of the organs allowing the interchange of infectious processes. The same germ, especially the gonococcus, produces disease in both rectum and genitals, *i.e.*, in the mucosa.

3. It is due to the relation and condition of the veins of both organs. There exists a double venous circulation with valveless veins.

4. The disease in one of the organs produces changes in the other. The reflex action in one organ produces disturbances in the circulation of the other organs, as anæmia, congestion, and emigration of microbes or their products. The congestion may also dilate and elongate veins, destroying their healthy spiral condition. Also the rectum is depleted by two systems of veins, and the portal, with part of the other system, possesses no valves. The same venous trunk depletes at times both rectum and genitals.

5. It is due to muscular trauma, which disseminates the microbes or their products to different regions of the pelvis.

6. It is due to the fact that neuro-vascular perforations exist in the partitions between rectum and genitals, allowing disease to travel on those lines, especially aided by the surrounding lymph sheaths.

7. The close relation of rectum and genitals should suggest a careful examination of both apparatuses by the physician.

On the Osteoplastic Treatment of Congenital Encephalocele.—Drs. Neugebauer and Ostran (*Centralblatt für Chirurgie*, 1897, No. 46) describe a case of encephalocele situated near the root of the nose, treated by sewing a skin-periosteal-bone flap over the tumor. The case seemed cured, but after two years' time there is now a non-pulsating swelling in the place of the original encephalocele. It is produced by the pressure of the growing brain against the flap, causing the latter gradually to give way and to become arched. Thus the cosmetic effect has not been permanent, though the tumor was prevented by the operation from growing.

I.—A WORD OF WARNING AND ENCOURAGEMENT TO THE GENERAL PRACTITIONER AS TO THE MANAGEMENT OF CASES REQUIRING SURGICAL AID. II.—THE DEPLORABLE STATE OF THE PRACTITIONER'S ECONOMICS, AND A SUGGESTION OF REMEDIES.

By LEONARD WEBER, M.D.,

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO POST-GRADUATE HOSPITAL; CONSULTING PHYSICIAN TO ST. MARK'S HOSPITAL.

I.

None of us who have been long in practice will differ from Dr. Charles McBurney when, at a recent meeting of the Practitioners' Society of this city, he advanced the statement that the permanent results of surgical operations would be greatly improved if the surgeon were always called in as soon as, and not an hour later than, appeared to be indicated by the symptoms of the case. Some very nice *points d'excuse* on the part of the patient as well as of the physician were brought out in the discussion; it is not my desire to add to them, but to state just a few cases of recent experience with regard to malignant disease of the mamma only, in each of which I gave an early note of warning to my patient and soon insisted upon a radical operation being done, without losing the confidence of the patient or having her swerve from the right road for a minute. And it may be said right here that, though the results obtained have been quite satisfactory to all parties, yet I am conscious that in these cases and in others I might have done better by being still more timely in asking the patient's consent, thereby not only facilitating the surgeon's procedures but greatly improving the chances of a permanent cure.

Case I.—Mrs. W——, fifty-two years old, widow. Large scirrhus of the left breast, that had been growing for more than two years, involving the pectoralis major muscle and all the axillary glands. Her daughter said: "Please do not tell my mother that she has a tumor, and do not speak of a possible operation; she would die from fright, and would not listen to any advice of operation." Not having seen the lady before, I spent half an hour to elicit her history from her and reassure her, and another half hour to examine her all over most thoroughly, and then said to her: "Madam, you have a malignant growth of the breast, with the same disease already established in your armpit. You are in great danger of getting this disease transported into your entire system. Your only chance lies in a speedy removal of the entire growth, if possible." Her consent was obtained before I left the house, and two days later the extensive operation was done by a surgeon whom I knew to be fully competent to proceed radically without hesitation, but without rashness. This is a matter of two years ago now, and, strange to say, the patient has suffered no visible relapse.

Case II.—Miss B——, forty-five years old; still regularly menstruated. No history; strumous diathesis (not a misnomer, if properly understood). She came to me first a year ago. She then looked very poorly nourished and felt generally miserable. The badly ingrown big-toe nails, which she came to have treated, I removed, and dressed the ulcers and wounds about her feet; I also treated her generally, until at the end of three months she was in a fairly good condition. She then said that, before staying away for good, she would have me look at her left breast; she thought there was a lump in it, but it did not hurt her a bit. Finding a rather small, hardish, flat tumor directly underneath the nipple—the latter a bit retracted, but every tissue around the same normal—I said to her: "Well, there is a growth there which may have to

be removed later on; take Fowler's solution for the present, and come back after a while." That was not good advice, and I regret now to have made so indefinite a statement; because, as patients are very apt to do, she stayed away, keeping on taking five drops of Fowler's solution t.i.d., on which she seemed to thrive, and when she returned to me three weeks ago she looked remarkably well. But the cancer? Had it remained idle in the mean while? By no means. It was twice its former size, and, pushing the fingers under the breast from above and below, I could feel cancerous nodules in the muscle and also in the left axilla. The radical operation was skilfully performed, but the greater part of the pectoralis major muscle had to be taken away, and the axilla required entire cleaning out.

Now the rapid deterioration in this case may be considered a striking and a warning example to the practitioner as to other cases when of the same type. As they come to consult us, not infrequently a conversation ensues like this:

"Why, yes, to be sure, you are quite right; there is a little lump in your breast."

"Is it clogged milk ducts, doctor? I hope it is nothing bad!"

"Well, now, madam, the lump is neither tender nor painful; it is a fibrous growth at the worst. No need talking about an operation now. Take these pills and come back some weeks hence."

Now my second case and many others which I know of show that this is not the right way to proceed. We know that nine such cases out of ten are cancerous, and will grow sooner or later. I propose never again to mention the words inflammatory induration, hardened milk ducts, fibrous growths, and such like nonsense after examination—which we are apt to use only to gain time; in doing so we belie both ourselves and the patients, we bewilder them, and we lose them. We must say to them at once: "There is a suspicious tumor present that needs to be looked after twice a month at least;" and let that looking after be a thorough and honest piece of work, for the accomplishment of which tact, skill, and experience are indispensable.

Case III.—Mrs. S. S——, fifty years old. No history; married when young; had one child. Her husband dying when she was about twenty-five years old, she went into domestic service and continued in it to the present day. She lost considerable blood at the time of her menopause, five years ago, but managed to get back into good health again, and continued therein. She went to Europe last summer to see her relatives, and, on returning in September, was under my treatment for rheumatic conjunctivitis and dyspepsia. In November she returned to me and said that she had slight lancinating pains in the left breast, and that she thought something hard had grown in it these last two months. Finding a small scirrhus with nipple retracted and at least two enlarged lymph glands in the axilla, I informed the patient of the presence of a malignant growth and insisted upon the immediate necessity of a radical operation. It was agreed to, and the mamma and infected glands were removed. Healing took place promptly.

It is not my purpose to relate more and similar cases, or to go into the subject of cancer of the uterus, the rectum, the intestines, the operable malignant tumors of the kidney, lymphatics, tongue, etc.; but I will say that, whenever and wherever I did my duty wholly and unflinchingly by my patient, stating kindly, distinctly, and with authority that a neoplasm was present which required early and radical removal, the party concerned did not take other advice behind my back, did not give me up, but almost always followed my counsel. To be sure, a good deal of earnest talk was sometimes necessary, consultations had to be had, a great many irrelevant questions had to be answered, inquiring friends had to be reckoned with, and all that; but what are we good for unless we are ready to do the many things that may be required in order to get the best thing done for our patient?

Now as to the economics that result from telling the patient the truth so far as necessary and in the proper way, or from withholding the same for fear of losing the case. My experience has been that the man who is afraid of losing his patient by telling him what he and his friends ought to know and know quickly will soon lose the case and a bit of reputation besides; the man who will say what is right, without twaddling and without adding rose-colored statements, will keep his patient and increase his practice. Of the moral aspect of the question I will not speak, because it is not within the scope of this paper.

There is, however, a question of finance in turning our cases over to the surgeon, of which I will speak. Time was when the surgeon performed his operation, dressed the wound, and the attending physician carried out the after-treatment. That such division of labor added materially to the regular income of the family doctor none know better than we older practitioners who lived and worked during that period and profited by such arrangement. Modern surgery has changed all that, and it is of little concern to the practitioner whether the surgeon operates on the case in the patient's house, or takes him to his private clinic, or gives him a private room at the hospital where he is on the visiting staff. The entire after-treatment is done by the surgeon, or his assistant, or even his specially trained nurse; the doctor is out, absolutely out of the case. He may make a friendly visit now and then, but his self-respect will soon make him discontinue these also. He may see the patient again when he is able to be about, or he may not see him again at all. Unless there is a previous understanding between him and the surgeon—and I have heard it said that such things are—the surgeon has the glory and everything besides; and the doctor—well, he may sleep soundly on a clear conscience.

Why is this so? No surgeon can make use of an assistant or a dresser who is not thoroughly skilled and experienced in the work; to be so skilled the physician must receive special instruction in hospital or private clinic for at least two years. A small minority get this and are consequently well equipped for serving as surgical assistants, but the majority of practising physicians lack such training, and consequently are not fitted to help the surgeon. I see no reason why a great many more young men should not, during their course of study, learn as much at least as a first-class surgical nurse in taking charge of the after-treatment of a great many surgical operations. It can be taught them, and the necessary course for such instruction ought to be made obligatory in the medical colleges, if it be not so already.

II.

A word now as to the gradual but decided reduction of the doctor's earnings and some of the causes thereof may not be out of place. I am far from denying that the abuse of medical charity at the hospitals and dispensaries, particularly the latter, is harmful to the private practitioner, and I believe that there should be no more dispensaries than the number of the poor of the city requires, and that these institutions be supervised by the State Board of Charities. But will the accomplishment of the necessary reforms in that direction benefit us greatly, as a good many seem to believe? I do not think it will, because such reforms remove but one cause of the present financial distress among doctors, and leave other influential ones untouched.

(1) No matter how far we may succeed by forced or voluntary altruism in modifying the consequences of some of Adam Smith's laws of economics, we cannot controvert the laws of trade, we cannot increase the supply of an article far beyond the demand for it and not diminish the value of that article at the same time. The production of medical men has gone far ahead of the actual demand for their services, and is out of all proportion to the increase of population of the United States, in comparison with that of other civilized countries. The country cannot support so many doctors, and therefore the State legislatures, if not the Congress of the United States, ought to pass laws regulating and limiting the establishment of medical schools, of which there need not be more than one to every million of inhabitants; and all now existing medical colleges ought to be made to take out a State license, the granting of which in any case should depend upon satisfactory proof being furnished by said medical college to the State that it maintains the recognized standard of didactic and clinical instruction and possesses the plant required for the purpose. Any medical school not coming up to the required standard ought to be abolished without delay.

Further, the study of medicine for the purpose of making a living out of the practice of it, may, indeed, be undertaken by any one who has the sense to learn the art and science and the means to look on until the living comes to him in time. But all those who lack these means must be dissuaded from entering an overcrowded profession.

(2) Specialism has come to stay, and is so well recognized already by a great many laymen that a number of them never think of sending for the family physician when a surgical case occurs in the house, but to the surgeon; and to the oculist when there is the least thing the matter with the eye; to the dermatologist in skin disease; to the laryngologist, otologist, etc., as occasion may require. That the well-to-do women are confined by specialists and go to the gynæcologists without a previous understanding with their family physician, goes without saying. That this establishment of specialism in the practice of medicine will be disestablished in the near or distant future may perhaps be believed by some, but I am not among those who so believe. Nay, it will surely continue to exist and prosper, the more so as its value is also well recognized by the general practitioner, who is only too apt to consult the specialist himself when there is the least thing the matter with him. Why should not the public follow his example? In my judgment, the income of the doctor is reduced by the competition of the specialist as much as by the competition of the fellow-practitioner; perhaps more. The city practitioner in particular may take this fact well to heart, and cultivate some specialty as he gets along in practice. Besides the great satisfaction he will have in becoming an expert in the practice of some special branch of his art, he will also be better off in the goods of this world.

And there is another condition of things, the bringing about of which has reflected great credit upon the doctor, but also helped to reduce his earnings. I mean the better and healthier mode of living, the improved sanitary surroundings, the out-door life of the people, and their increasing cleanliness. The rules and laws of health and life have been preached by the physicians in public and in private all these years, and the inspectors of the board of health have insisted upon the observance of the same by the poor. Think, for a moment only, on the daily supply of pure water, milk, and food to the inhabitants of this city, and compare what we have now with what we had to put up with twenty-five years ago! No wonder the public is better now, and the time may come soon when the functions of the general practitioner will be mainly those of the sanitary inspector, who looks after the health of his clients, gets his office free of rent, and is paid a fixed salary that is to come out of the money contributed by the taxpayers of the city.

When I began thirty-five years ago, I started practice, as many others have done, in the populous districts of the lower parts of the city, and attached myself to a dispensary—the Northern, it was—where I did surgery for three years. Did the dispensary work do me any good? Decidedly; I got a good deal of experience in minor surgery, and indirectly some private patients, who were sent to me by the poor I took care of at the Northern. Hundreds of men have done likewise and done well. Can a young man travel the same road now? I believe so, though the path may be much more rugged and difficult to find. If he takes umbrage at such low beginning, and lacks a string of cousins and aunts to help him along and sing his praise among the well-to-do, then he may betake himself "*procul urbe ut prisca gens mortalium*"—and it will not be a bad move, if he soon learn to know the ways and tricks of the rustics. They are apt to take kindly to the new doctor; they will take him in softly too, but he will triumph in the long run, if he be smart and understand his business. And the practice of medicine is a business as well as an art, and fully as difficult to succeed in as any other.

There may be other things worthy of discussion in the consideration of the economics of the general profession; let others point them out. I am conscious of having said what I believe to be true, and have essayed to make some suggestions which might be of service to the general practitioner. And, as I am one of them, it is to be hoped that my remarks may be kindly received and impartially read.

25 West Forty-Sixth Street.

THE RELATION OF THE OPERATOR TO THE ANÆSTHETIST.[1]

By SALING SIMON, A.B., M.D.,

former chief resident physician, arapahoe county hospital.

Implicit confidence on the part of the surgeon in his anæsthetist is essential to the success of an operation and safety of the patient; and when this exists no difficulty ought to arise. Unfortunately, in most hospitals one of the younger internes is, as a rule, selected to administer the anæsthetic. The operator accustomed to having a novice give chloroform or ether for him is kept on the *qui vive* while performing the operation and watching the administration of the anæsthetic. Such a condition of affairs is not conducive to the best work of the surgeon. If the anæsthetist is one who forgets his patients in his anxiety to watch the operation, the surgeon is certainly justified in giving some attention to the patient; but if the former is a careful man, who fully realizes the importance of his position and gives his entire attention to the patient, the operator should let him alone. Nothing is more annoying to the one giving the anæsthetic than to be continually warned by the surgeon to watch his anæsthetic, when his undivided attention is given to the same. On one occasion recently, while I was witnessing an operation in one of New York's hospitals, the operating surgeon kept continually yelling at the interne who was administering ether and seemed to be doing his work well. "For Heaven's sake, don't let the man die on the table!" "Don't crowd the ether!" etc., were some of the things hurled at his head, although at that particular moment and for fully a minute previous the cone had been removed from the pa-

[1] Read before the Colorado State Medical Society, June 17, 1897.

tient's face; in fact, the operator did not appear to be watching the patient's condition, but simply from force of habit, I suppose, or absence of students, had to keep his tongue in motion.

It seems to me an important part in a faultlessly conducted operation, after a competent anæsthetist has been selected, to leave the administration of the anæsthetic and the patient to his care. He should, except under unusual circumstances, be allowed to choose the anæsthetic or change it when he considers it expedient. It is almost unnecessary to add that the use of stimulants while the patient is upon the table should be left entirely to his discretion. The duty of the operator toward the patient, as far as the administration of the anæsthetic is concerned, ought to end with the selection of the anæsthetist.

The position of the anæsthetist is not an easy one. Upon him depends not so much the success of the operation (for every operation is successful and beautiful even though the patient die), but the recovery of the patient. He should be so preoccupied with his patient and anæsthetic as to be almost oblivious of everything else going on in the room. He should use the least amount of anæsthetic necessary to bring about the degree of narcosis desired by the surgeon. (And let me add that he should avoid so saturating the patient with the anæsthetic as to require an hour or more after completion of the operation for the latter to come out from under its influence.) If he finds the patient failing, after having resorted to the usual methods of stimulation he must warn the operator in due season, in order to give the latter a chance properly and rapidly to conclude his operation. It is in cases of the kind mentioned that the judgment of the anæsthetist will be most severely tested. He must be careful, on the one hand, not to alarm the operator unnecessarily, and, on the other, not take too many chances with the patient. When any doubt exists in his mind, he should briefly and quietly state the patient's condition to the surgeon, and thereby to some extent divide the responsibility in case the latter wishes to continue. But not for one moment should he relax his watchfulness or feel that in so doing he has shifted the burden of responsibility upon other shoulders than his own. A story—and let us hope it is only a story—is told of a young interne who, while giving an anæsthetic, warned the operator several times to desist, as the patient was doing badly. At each warning the surgeon glanced up for a second, made light of the young doctor's alarm, and continued his operation. At its conclusion the surgeon looked up and asked, "Doctor, how is the patient?" and was met with the laconic reply, "She has been dead for the past five minutes."

An excellent solution of the problem, and what ought to be the desideratum of every surgeon, would be the professional anæsthetist. It is doubtful, however, whether one taking the work up as a specialty could make a living at it alone; and especially is this true in the smaller cities.

The difficulty arises from the fact that every physician gives anæsthetics occasionally, and, no untoward results following, he believes it to be a very simple and easy matter. He forgets that he cannot judge of its dangers from his limited experience.

The time may come when the medical profession will recognize that proficiency in the administration of anæsthetics requires special training, and then the specialist, the professional anæsthetist, will supply a long-felt want.

303 Jackson Block.

Mammary Carcinoma.—Set up an experimental cirrhosis by injecting dilute alcohol about the tumor. Twenty-five cases are reported thus treated.—Nasse, *Virchow's Archiv*, 146, 2.

THE TREATMENT OF CRUSTA LACTEA, OR INFANTILE ECZEMA.

By W. P. Kistler, M.D.,

Allentown, Pa.

The occurrence of this affection in infants and children under four years of age is so common, its clinical appearance so marked, and the opportunity for its complete observation by every practitioner of medicine so frequent, that the writer will not unnecessarily take up space for its description.

The large number of cases treated, and the more than ordinary success obtained in its cure, prompt me to give the treatment pursued during a busy practice of over thirty years. Milk tetter occurs among the rich as well as among the poor, and is a most annoying affection, not only to the little sufferer, but to the mother or nurse who has charge of the case, when sleep is so frequently disturbed by the child's distress. In the etiology of infantile eczema, an inherited or congenital tendency to eczematous inflammation may exist, and such cases are as a rule more difficult to cure than cases in which the active cause can be demonstrated.

There are three chief indications to be fulfilled in attempting to cure this distressing complaint; namely, elimination, palliation of local distress, and correction of malassimilation and restoration of strength—which latter are, indeed, the main factors.

For elimination, calomel in purgative doses—one to two grains (preferably tablet triturates), according to age—the object being to stimulate the liver and to obtain a perfect clearance of the stomach and bowels; the dose to be repeated according to circumstances—once, twice, or thrice a week, as the patient's condition may indicate.

For alleviation of local distress, itching, etc., the benzoated oxide-of-zinc ointment is an old but capital application to soothe and protect the skin. The following is another excellent dressing, viz.:

℞ Salicylic acid	2	parts.
Bismuth subnitrate	40	"
Cornstarch	15	"
Ointment of rosewater	100	"

These ointments should be spread thickly on pieces of muslin and carefully applied, especially in the moist variety. When there is merely a dry squamous form of the affection present, and in the face, the ointment can be rubbed over the surface of the skin. These salves may be repeatedly applied until a thick, white, and rather dry coating forms upon the surface of the skin, which greatly lessens the itching and the redness, and allows a healthy epidermis to form. Soap and water are powerful agents to aggravate this existing inflammatory condition, and the frequent washing of an infant or child affected with eczema is to be strenuously interdicted.

The third indication, restoration of strength, is accomplished by correcting the malassimilation and restoring the blood to its normal condition. The best agent for effecting this is that valuable alterative tonic—arsenic; Fowler's solution, in doses of one to three drops, according to age, may be given. It should invariably be conjoined with iron; the ammoniated citrate, so readily soluble in cold water, combined in proper doses, is a very convenient and efficient preparation for this purpose. The same should be administered three times a day. The elixir of gentian and tincture of chloride of iron in suitable doses are also an eligible tonic and stomachic in this class of patients.

Hygienic and dietetic measures must likewise not be neglected.

Progress of Medical Science.

A New Method of Intestinal Anastomosis.—The possibilities in surgery, and especially in abdominal surgery, appear to be practically illimitable. But a few years ago, and the prediction that the operation for removing the entire stomach could be performed with any degree of success would have been scouted as the vaporings of a dreamer. Now that this apparently impossible feat has become an accomplished fact, it would be rash to assert that any operation, however radical, is too difficult for the surgeon to attempt with the hope of good results. This advance in practical surgery, in which our country has played a satisfactory part, is undoubtedly one of the most striking features of recent years. Almost every week some novel mode of performing an operation is suggested or tried. This is as it should be, for it is in experiments that the path which leads to final success lies. Dr. J. Shelton Horsley, in the *New York Polyclinic* for December, describes a new method of intestinal anastomosis that has occurred to him, and which has been tested on animals and the cadaver. From a perusal of this article, it would appear that the means proposed by Dr. Horsley are both feasible and simple. These are as follows: "After the incision in the abdominal wall, the diseased intestine is drawn well out of the abdominal cavity, and sterilized tapes are placed through the mesentery several inches from the point to be resected, and tied round the intestine just tightly enough to check the fæcal flow. Fæcal matter is stripped from between the tapes before they are tied. The intestine is resected, bleeding points in the mesentery are secured with artery forceps and ligated with silk, and the ends mopped out with moist bichloride sponges. The mesentery is incised for several inches at right angles to the intestine, or a V-shaped section removed to facilitate the subsequent manipulation. The ends of the bowel are then placed side by side, opening in the same direction and being in contact along their free surfaces opposite the attached mesentery. A pair of artery forceps inserted in the ends and clamped holds them in this position. A finger of the left hand is inserted into one end of the intestine and the thumb into the other, and over them as a bobbin a Cushing suture of fine silk in an ordinary cambric needle is commenced. The first stitch approximates the portion of the two limbs of the intestine near the mesenteric attachment. The suture is then carried obliquely for about two inches, when dealing with the small intestine, to the border opposite the mesenteric attachment, and continued over the other side, where it stops at a place corresponding to its point of commencement. Here the needle is left on the thread, and an artery forceps, padded with sterilized gauze to prevent injury to the thread, seizes it where it emerges at the last stitch. This keeps the sutures tight. The bowel is now partly everted, exposing a U-shaped septum, grasped by the artery forceps first applied. This septum is cut away with curved scissors, leaving a margin of one-third of an inch. An overhand suture of silk in a curved needle is then commenced at one edge of the 'shelf' left by cutting away the septum, and is carried through all the intestinal coats. When the suture reaches the end of this shelf, it is continued by slightly invaginating the rest of the resected ends, which consists of about one-fourth of the entire circumference. It terminates at its point of commencement. The first line of sutures is now finished by continuing it about one-fourth of an inch from the overhand suture. The incision in the mesentery is closed, the intestine lightly sponged with gauze wrung out of hot sterilized salt solution, and dropped back into the abdominal cavity." It is claimed as a special feature of this manner of operating that all fear of stricture is removed. Experiments made on three dogs by Dr. Horsley resulted as he had anticipated.

Know Syphilis in all its manifestations and relations, and what remains to be learned will not stretch the pia mater of a megalocephalic senior student.—William Osler.

The Nature of the Cells in Soft Moles and their Relation to Malignant Growths.—Fleshy nævi have long been looked on as epithelial inclusions in the connective tissue—misplaced embryonic growths, according to Cohnheim's view. But this does not exhaust the interest in such moles, since with them is bound up a larger scientific question—how certain malignant tumors are to be regarded, which have sometimes been classed as sarcomata, sometimes as carcinomata. Should, then, the epithelial nature of the nævus cell be accepted by the majority of anatomists, this will necessarily open the way for the pathologist, when it is seen that any other view is irreconcilable with so many accepted pathological theories. The nævus cells, according to Unna (*Deutsche med. Zeit.*, June 21, 1897), are found in very various numbers in all soft moles, in the form of solid groups, balls, cords, and larger masses, more rarely single. They are simply deposited without the intervention of any investing membrane in the connective tissue, which, except that it contains fewer elastic fibres, is otherwise normal. These cells are distinguished by two peculiarities, more manifest near the surface, where they are less compressed: First, the vesicular form and considerable size of the nucleus; and second, the complete absence of fibrillar connective tissue beween the cells within the groups. They differ from the surface epithelium in that their protoplasm is less amenable to staining, and in the absence of prickles; thus they have more affinity with gland epithelium. From the developmental point of view, the nævus cells are only snared-off epithelia deposited in the connective tissue. This can be determined by examining such moles taken from the cadaver of newborn or young infants, in which can be seen: (1) epithelial proliferation; (2) metaplasia of the epithelium, namely, a structural and tinctorial change in the epithelial protoplasm: and (3) the snaring off of the epithelium and its deposition in the connective tissue of the corium. Variations in the degree of these account for differences in the forms of the nævi of children. These can be divided into four categories: (1) those with simple epithelial proliferation; (2) those in which to this are superadded metaplasia, and snaring off after a thoroughly concordant fashion; (3) those in which metaplasia of the prickle cells follows closely on the epithelial proliferation, but the snaring off of the metaplastic parts is disproportionately delayed; (4) those in which the epithelial proliferation, the metaplasia, and the separation occur so harmoniously that there is no increased accumulation of epithelium on the surface of the nævus. It may be objected that the cell masses in the cutis are not epithelia, but endothelia; but three circumstances militate against this. There is nowhere any indication of cell proliferation in the cutis and vessels, which is necessary as the basis of a connective-tissue theory of the origin of the cell masses. And not only are changes to be found in the surface epithelium, but also in that of the hair follicles and sweat ducts. Besides, the prickle layer in these organs is proliferated here and there, and, more than that, altered metaplastically. This in addition favors the hypothesis that the nævus cells in the adult are in part derived from the prickle layer of the epidermic appendages.—*The Edinburgh Medical Journal*, January, 1898.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 12, 1898.

NATIONAL QUARANTINE AND THE MARINE HOSPITAL SERVICE.

THE discussion concerning the advisability of a national health law has culminated in a consensus of opinion on the part of the general public, of the health authorities, and of the medical profession, that the time has come for an ultimate settlement of the questions at issue. To this end several bills are now before Congress, advocating governmental control of quarantine and the consistent adjustment of State rights in preventing the spread of disease from one commonwealth to another. The experiences of widespread epidemics, notably that of yellow fever last summer, and the inability of the different health boards adequately to meet the then existing emergencies, have proven the urgent necessity for more stringently protective regulations than at present exist. The fundamental difficulty has been the apparent impossibility of reconciling merely local differences with the general good. Each State, having a sanitary code of its own and being naturally jealous of its legal rights, has fought against a proper understanding of mutual interests and the consistency of adopting proper means to desirable ends. It is perfectly obvious that, in order to harmonize such more or less radical disputes of authority, there should be created some centralized power in the general government, which should control every part of the widest territory or the longest stretch of coast, and compel each State to do its part in the realization of a perfected system of common protection.

To accomplish such a purpose, very many efforts have been made during years past by sanitary and medical organizations, but thus far there has been no reasonable agreement on the fundamental principles and on the practicable and consistent management of necessary details for effective and comprehensive work. The medical profession, with a laudable effort to gain proper recognition in such a movement, has been overambitious in claiming too much for itself at the start. While it would be eminently desirable that a distinct department of public health should be created, having a cabinet officer at its head, it is quite evident, considering the state of public opinion at present, that there is no appreciation of the necessity of such a radical and far-reaching measure as yet; and it is also quite clear that the profession must grow up to the situation rather than force it. This disposition on the part of the framers of many of the bills is the real stumbling-block to all effective legislation on the subject. It has been so in the past, and it is so in the present. It is the old story—when we ask for too much we are likely to get nothing. Every one who has studied the attempts at legislation in the direction of national quarantine must have been impressed with their complexity, impracticability, and cumbersomeness.

There is just now not so much a necessity for educating the public in sanitary matters as for perfecting suitable police regulations for threatening epidemics. Thus it would naturally appear to be reasonable to elaborate, strengthen, and amplify what we may already have in that line, rather than to aim at some new, untried, and obviously unwarrantable measures. From such a point of view the bill of Senator Caffery, "granting additional quarantine powers and imposing additional duties upon the Marine Hospital service," deserves the support of every one who may hope for a logical settlement of the great question at issue. This bill has for its purpose such a development of the Marine Hospital plant as will make it possible for the general government efficiently to control all maritime and inland quarantine, and is framed on the practical basis of aiding and advising the local authorities and not interfering with them, unless in cases of emergency or when large districts of country are affected and when a general impartial and uniform system of protection is demanded. The secretary of the treasury naturally remains at the legitimate head of the department. Much as it would compliment the medical profession to have a physician in such position as a member of the cabinet, the proposed measure is the next best solution of a question concerning which there are many pros and cons. The secretary has already supreme control of maritime customs, and can, on sufficient grounds, refuse the entry of any vessel bound for our ports. When to such power that of enforcing quarantine is added, it is easy to conclude that both functions can work together harmoniously and consistently. Then, again, there can be no question, in this instance, regarding the constitutionality of so-called invasion of State rights, as Congress has the right to regulate commerce and can interfere with anything that pertains to it.

One very forcible argument in favor of the bill is the fact that the Marine Hospital service, having done so much in arresting and preventing epidemics, is fully competent to exercise increased powers in the line of work with which it is already perfectly familiar. With such great interests at stake as the health of the entire nation, there will be no possible temptation to make distinctions in favor of one or other district, but all can come under a uniform regulation, "as far as climatic conditions will justify."

The main opposition to national quarantine comes quite naturally from local authorities which are jealous of the privileges of revenue and of political patronage. This is evidenced by offers on the part of several

States to purchase the present quarantine plants of the government and manage them as independent establishments. The pecuniary measures which comprise the levying of arbitrary and excessive fees on commerce, and which are the main ones considered by the different State quarantines, are to the last degree oppressive, burdensome, invidious, and unnecessary. By a new order of things there will be no call for special fees, and all the ports of entry will be on an equal basis as regards quarantine regulation. The advantages of the latter system are already proven in those localities where only national inspection prevails, by the fact that increased trade is naturally attracted to such favored ports to the exclusion of neighboring ones not so favored. Thus it will be seen that millions of dollars can be saved to commerce, which are now demanded on the purely technical ground of State rights to collect special fees.

It is useless, however, to multiply arguments in favor of national quarantine. The real question that concerns us now has reference to the best and readiest means to the desirable and imperative end. The best answers to objections urged against all bills heretofore presented are very effectively, consistently, and practically given in the admirable, far-reaching, comprehensive, and just provisions of the Caffery bill. The Marine Hospital service eminently deserves every opportunity for increased usefulness and good work. Even with its limited resources it has made an admirable and unimpeachable record. The profession and the public should be ready with their endorsement at the time when such is so much needed to make all the really necessary quarantine reforms within the reach of ready realization.

THE LATEST FRILL ON THE NEURON THEORY.

SCIENCE has found the seven-leagued boots, and to-day covers more ground in one stride than she once did in a century, when she trotted like an obedient housedog in the footsteps of the fathers. This is very enterprising in science, and of undoubted benefit to those whom she is hastening to aid; but there is a tendency to get out of breath among the humble devotees who try to keep up with her. Having reached a satisfying, all-embracing conclusion on some doubtful question, these devotees are tempted, like Ulysses' crew on reaching the land of the lotus eaters, to—

> "Sit them down upon the yellow sand,
> And say, 'We will no longer roam.'"

But even while they are preparing to sit down and enjoy the prospect of a new point of view, science takes another stride; and the satisfying conclusions, the well-constructed theory, and the point of view vanish into thin perspective, and become things of a far-off yesterday.

It is only within the last half-decade that neurologists have begun to interpret diseases of the nervous system in terms of the neuron, and now a recent contribution from a well-known investigator in histological science, working with methods on which he has spent years in elaborating and perfecting, suggests a new point of view, and, should his ideas prevail, another reconstruction must be accomplished.

In his latest communication, F. Apathy, in the "Mittheilungen aus der zoologischen Station zu Neapel," vol. xii., 1897, "Das leitende Element des Nervensystems und seine topographischen Beziehungen zu den Zellen," presents a series of observations with numerous illustrations which merit special attention.

Among the many erudite things discussed in this paper, the structure of the protoplasm of the nerve cells is most vigorously expounded. The author studied the nervous systems of the leech and the earthworm among the invertebrates; the angler, the triton, rabbit, and ox among the vertebrates.

Apathy believes that both histologically and histogenetically two kinds of nervous elements are to be distinguished, and he designates them as the "nerve cell" and the "ganglion cell." The nerve cell develops neuro-fibrils which conduct nervous impulses, and the ganglion cell produces the force necessary for the conduction of these impulses.

These neuro-fibrils are the agents in the upsetting of the neuron theory as it now stands; for, according to Apathy, a neuro-fibril or bunch of fibrils may originate in a single nerve cell and traverse the bodies of several ganglion cells, becoming, it may be, more attenuated as it extends, until a single fibril may end in a sense or muscle cell. Thus the neuro-fibril acts like a long telegraph wire, with relay stations in the shape of ganglion cells, which help the impulses along.

According to this investigator, five different methods of communication between ganglion cells have been found, in the most important of which the axis-cylinder processes of two cells connect by means of various ramifications, forming an anastomosing reticulum.

As to the path taken by the neuro-fibrils and their behavior in the ganglion cells through which they pass, Apathy describes two types—(1) larger cells, (2) smaller cells. In the first type the neuro-fibrils enter into what he designates as the "chromatin zone," one of seven distinct zones which he describes as being present in the ganglion cell of the leech. In this zone the neuro-fibrils break up into a fine reticulum of primitive fibrils, and then again recollect on the opposite side of the ganglion cell to go on in the cell process. In the second type of cells the neuro-fibrils coming into the body of the ganglion cell break up into two series, and enter his fourth and seventh zones, the "outer chromatin zone" and the "perinuclear zone"; these two zones representing concentric hollow spheres, connected by fine radial neuro-fibrils.

Apathy tells us that the cellulipetal fibrils pass into what he terms "the perisomal latticework" (a part of the outer chromatin zone), and then pass along the radial fibrils to his "perinuclear zone" or the boundary between his fifth and seventh zones; after ramifying in this latter zone they collect and pass out as a single, thick, cellulifugal neuro-fibril. "No primitive fibril passes through the body of a ganglion cell without being broken up into a reticulum in some part

of that cell and again collecting into a fibril," and "no entering primitive fibril ever terminates within the ganglion-cell body," nor "does any primitive neuro-fibril originate within the body of a ganglion cell."

If these dicta be true, even the modern neuron theory must soon take its place among the many outgrown garments which science has worn for a time and then laid aside.

CHOLERA IN JAPAN.

In view of the important events happening now in the far East, any information concerning Japan is of interest. Dr. W. F. Arnold, of the United States navy, has published in the "Report of the Surgeon-General of the Navy for 1897" a most valuable paper on cholera in Japan. It is stated that the first appearance of cholera in Japan was in the year 1822, and that the disease was introduced into the country by means of Dutch ships from Java. The second epidemic outbreak, according to Japanese accounts, was from 1858 to 1860, when, if local traditions can be relied on, it caused several hundred thousand deaths. Davidson, of London, asserts that one hundred thousand deaths occurred in Tokio in one month. With the third epidemic in Japan, the reliable history of the disease begins. This happened in 1877, and was ascribed by the Japanese to an English man-of-war which put in at Yokohama, with one of her crew dead from cholera. The fourth epidemic broke out in 1881 and 1882, and the fifth in 1885 and 1886. The sixth outbreak of cholera on a large scale was in 1891 and 1892, and the seventh and last, in 1895, was without doubt a result of the war between China and Japan. Although an enormous amount of work has been done among the Japanese in the way of instructing the common people how to avoid infection with cholera, yet there are many risks to the public health maintained everywhere in the way of primitive waterclosets, while the water supply in the large towns is defective. An unusual incident of the efforts to instil into the minds of the common people the necessity of cultivating habits likely to afford them immunity from cholera has been, says Dr. Arnold, the establishment of a microscope in a temple. It is said that the demonstration of the living organisms in water to housewives was much more impressive than were lantern exhibitions or any other means of illustration. The opinion of Davidson that cholera is of late years endemic in Japan is not in accordance with the conclusions arrived at by Dr. Arnold, who says that "it would appear that the conditions of life favor the survival of the cholera vibrio the least in Japan, where the dark, hot, and crowded living-rooms of the Chinese do not exist. In general the life of the cholera vibrio is longest in dark, moist places at room temperatures."

On the other hand, Dr. Arnold goes on to say: "The primitive arrangements serving as waterclosets throughout Japan, the conservancy of human excrement, and the liability of many water supplies to contamination, are conditions as favorable to the requirements of the cholera vibrio as could have been supplied by design. Under these circumstances, there would appear to be little difficulty in understanding both the customary subsidence of cholera in Japan in the late autumn and the comparatively numerous but widely scattered cases of the year or years succeeding. Other countries, in which infection is more infrequent, have shown, and are now showing instances of the survival of cholera vibrios that are more noteworthy than any of the recent experiences of Japan. They are not expected to become permanent homes for the cholera vibrio, whence it may be carried to yet other countries; and I doubt if Japan has much to fear in this direction."

FRUIT CURE.

According to a celebrated health expert, blanched almonds give the higher nerve or brain and muscle food, and the man who wishes to keep up his brain power will do well to include them in his daily bill of fare. Juicy fruits give more or less the higher nerve or brain food, and are eaten by all men whose living depends on their clearheadedness. Apples supply the brain with rest. Prunes are said to afford proof against nervousness, but are not muscle feeding. They should be avoided by those who suffer from the liver. But it has been proved that fruits do not have the same effect upon everybody. Some men cannot eat apples without suffering from acute dyspepsia. "Fruit cure" is a form of treatment which is quite the rage in continental Europe now with persons suffering from real or imaginary maladies.

The *New York Times* says, in reference to this one of the latest fads: "In the tenth century, an investigator has discovered, many medical authorities became enthusiastic in their writings over the remarkable curative virtues of grapes; while a certain Van Sweeten, of a more modern date, is said to have recommended in special cases the eating of twenty pounds of strawberries a day. The same gentleman also reports a case of phthisis healed by strawberries, and cites cases in which maniacs have gained their reason by the exclusive use of cherries. These instances savor rather of the ridiculous, but there is no doubt that the so-called grape cure for indigestion and other evils is carried on in many places on the continent, and that people betake themselves to Meran, Vevay, Bingen, or to Italy and the south of France, with the intention of devoting six weeks to the cure, during which time they are expected to have gradually accomplished the feat of consuming from three to eight pounds of grapes daily. Grapes are said to exercise a salutary action on the nervous system and to favor the formation of fat—that is to say, when fruit of good quality is employed; if the grapes are not sufficiently ripe and are watery and sour, the patient may lose rather than gain weight. The valuable results obtained by a fruit diet in cases of dyspepsia are due to the fact that the noxious germs habitually present in the alimentary canal do not thrive in fruit juices."

That fruit is a most valuable article of food cannot be denied, and that many diseases may be greatly benefited by a diet largely composed of fruit is true

enough. It is a fact, too, that the majority of people eat more meat than they require. Meat eaten once a day is sufficient for a person not engaged in manual labor or who does not take much strong outdoor exercise. A large number of the complaints contracted owe their origin to the consumption of food which entails a greater drain on the gastric juices than the system is able to withstand. The cures attributed to the grape occur for the most part with those who are accustomed to high living, and are really owing to the fact that the organs of digestion are given a much needed rest. Semistarvation would answer the purpose almost as well. For the person whose work lies chiefly indoors, a mixed and varied diet is most conducive to good health.

THE MEASURE OF WORTH.

Is it true, as stated in a telegram to a daily journal of this city, that only mediocrities in medicine are well spoken of by their fellows? In commenting upon the opposition from his professional colleagues with which Dr. Péan met during his career, it is said that "the public may estimate the value of the physician by the amount of criticism he receives from his contemporaries."

This is a proposition which calls for refutation. It is an injustice to physicians, because of its glaring falsity. The shining lights in the medical profession, in this country at least, and we believe the statement holds good for France as well, are recognized, respected, and even revered. It would be a sad thing indeed if those who were spoken well of should have to be classed with the mediocre from whom "doctors have nothing to fear." Let no man deem himself great because he is opposed and censured. Let no man take it to heart if he be well spoken of. Physicians are not so unjust as would thus appear.

ANÆSTHESIA.

Anæsthesia is a subject whose interest never palls, but recently the attention paid to it has been greater than ever. Dr. Dudley Buxton a few weeks ago delivered a powerful address on anæsthetics before the Society of Anæsthetists in London. After reviewing in an interesting manner the history of anæsthesia and touching on the much vexed question of the cause of death from chloroform syncope, he gave it as his opinion that chloroform is a dangerous drug except when administered by skilled hands. The custom in England among many practitioners of using chloroform in a careless manner, by means of a cloth or towel, and without first measuring the quantity, was severely censured. *The Lancet*, commenting on Dr. Buxton's address, says that "anæsthesia has been practised from time immemorial—certainly from that convenient legal period 'beyond' the memory of living man."

In connection with these remarks it may be to the point to call attention to a short article which appeared in *Le Siècle* as long ago as 1881. This article states that a manuscript by Papin, so well known by his inventions for applying the motive force of steam, had been discovered at Marburg in Hesse-Cassel. The title of the work was "Traité des Operations sans Douleur," and it was stated to contain an account of "the different means that might be employed to deaden or rather altogether nullify sensibility when surgical operations are being performed on the human body. Papin composed this work in 1681, when filling the situation of professor in the University of Marburg, and in it he anticipated the effects produced in modern times by ether and chloroform. He communicated his idea to his colleagues in the university, but from them received anything but encouragement. In consequence he took such a disgust to medical pursuits that he gave up his profession as a physician and directed his attention to natural philosophy, in which he subsequently became so celebrated. The work in question is now in the private library of the Duke of Hesse."

THE ELMIRA REFORMATORY AND THE INDETERMINATE SENTENCE.

To do a little investigating, or have a little done, or change a few laws, is a perennial ambition that springs into life in the patriotic bosom of many newborn statesmen in Albany. It is much easier to tear down than it is to build up. Any crude hand, at one fell blow, may destroy the most sublime picture that artistic genius ever created.

The Elmira Reformatory is an institution for the scientific treatment of criminals. It is a place where boys and young men from sixteen to thirty years of age, not hardened criminals but usually tyros in crime, are sent and made to serve a sentence or undergo treatment for a length of time that is undetermined on their admission to the reformatory.

It has come to be a recognized fact in the science of penology that the criminal is sick, diseased, and that his reformation is to be sought through the cure of his malady. The Elmira Reformatory has been in successful existence for nearly a quarter of a century. It is claimed by the management of the institution that eighty per cent. of the young criminals committed to it for care and treatment leave the institution reformed and afterward lead useful lives as law-abiding citizens.

If this be true, and we have no cause for doubting it, since the results sought are so carefully and scientifically produced and conscientiously tabulated in the end, it is to be regretted that there appears to be arising a desire to rob it of its distinguished reputation by destroying its chief feature, namely, the indeterminate sentence.

The value of the indeterminate sentence to this institution can best be illustrated by a parallel case that would be this: A physician visits a patient sick with pneumonia and says to him: "You are sick; you must go to the hospital. I will send you there for twenty days," thus fixing in advance the date for the discharge of the sick man, whether he has recovered at that time or not. So with the Elmira Reformatory. It may take

one, or two, or three, or more years to cure or reform a criminal, and the determination of the date on which that will be accomplished cannot be fixed in advance; it must be left to the discriminative judgment of the skilled penologist in charge of the reformatory, whose business it is to treat the criminal as the physician treats his patient.

It is furthermore worthy of note that the governor of the State, in his last annual message to the legislature, called attention to the indeterminate sentence in the law governing this institution, apparently with a view to legislation that would effect its abolition. If it should be abolished, it would destroy in a great measure the chief value of the reformatory and would prove a serious calamity to the growing cause of penology everywhere.

The Elmira Reformatory stands second to none of its kind in the world, and it is hoped that such unwise legislation as the abolition of the indeterminate sentence may never come to pass.

News of the Week.

Pension Examining Surgeons.—The United States civil-service commission announces that on March 5, 1898, an examination will be held at Washington and at other places throughout the United States, for the position of pension examining surgeon. As the result of this examination, vacancies will be filled at Bridgeport, Conn.; Lynn, Mass.; Washington, Ind.; and Vicksburg, Miss. Applicants must be graduates of reputable medical colleges, and not barred by State or other laws. The subjects of the examination are as follows: Thesis, anatomy and physiology, physical diagnosis, general and special pathology, and surgery. The subject of the thesis will be upon some common medical theme, and each competitor will be required to write not less than two hundred and fifty nor more than five hundred words. Persons who are legal residents of the places where the vacancies exist will be given preference in appointment. Persons desiring to enter this examination should write to the United States civil-service commission at Washington for application blanks, forms 304 and 375, which should be properly executed and promptly filed with the commission at Washington. No applications will be accepted after the hour of closing business, on Friday, February 25th.

A Legacy for the Establishment of a Hospital.—By the will of ex-Chief Justice John Scott, of Bloomington, Ill., his estate, amounting to about $2,000,000, is to be held in trust for the benefit of his heirs until their death, when it is to go to the city of Bloomington for the foundation of a hospital.

The Hatfield Memorial Prize.— Messrs. Walter and Henry R. Hatfield have given in trust to the College of Physicians of Philadelphia a fund for the foundation of a triennial prize in memory of their father, the late Dr. Nathan L. Hatfield. Competition for the prize, which will amount to $500 or more, will be open to scientists and physicians of the United States, and the award will be made to the author of the best essay on a special subject containing deductions based upon original research. The award of the prize, as well as the selection of a subject, will rest with a committee of three appointed by the president of the College of Physicians.

The Lebanon Hospital Alumni Association.—At the second annual meeting of this society, held January 18, 1898, the following officers were elected for the ensuing year: *President*, Dr. Frederic W. Loughran; *Vice-President*, Dr. Edwin L. Rose; *Secretary and Treasurer*, Dr. M. L. Maduro.

The Association of American Anatomists.—The next meeting of this association will be held in December, 1898, in New York City. The president is Dr. Burt G. Wilder, Cornell University, Ithaca, N. Y.; and the secretary Dr. D. S. Lamb, 800 Tenth Street, N. W., Washington, D. C.

The Wooster Medical College, which is located in Cleveland, and is not connected with the Wooster University but with the Ohio Wesleyan University at Delaware, is to erect a new building, if satisfactory arrangements can be made with the Ohio Wesleyan authorities.

The National Veterinary Association will meet next year at Omaha, Neb., upon invitation of the Nebraska Veterinary Association which has just held its semiannual meeting at Lincoln.

The Register of Physicians of the Illinois State Board of Health will shortly be issued, and it is desired that it may be as correct as possible. Every licensed physician practising in that State is therefore to send his or her name and address on a postal card to Dr. J. A. Egan, Springfield, Ill. The number and date of the certificate should also be sent with the name and address.

The Sioux Valley Medical Association held its semiannual meeting in Sioux City, Iowa, on January 20th and 21st, under the presidency of Dr. Sherman, of Cherokee.

The Cumberland County (N. J.) Medical Society convened at Hotel Stephens, Vineland, January 11, 1898. The society was called to order by the vice-president, Dr. Judson. Interesting papers were read by Dr. Ware, on the "Old-Time Doctor," and by Dr. S. T. Day, on "Puerperal Eclampsia."

Dr. Samuel C. Busey, of Washington, who was elected to deliver the address on State medicine before the American Medical Association in Denver, has resigned the appointment on account of ill health.

The Society of the Alumni of the City (Charity) Hospital held its eighth annual dinner at the Hotel Savoy on the evening of Wednesday, February 2d. One hundred members and guests were present. The toasts were responded to by Dr. W. M. Polk, Rev. Dr. David Greer, Dr. Leroy M. Yale, Mr. Frederic Perry Powers, Col. E. C. James, Col. Richard H. Savage, Dr. Richard C. Newton, and Commissioner Keller of the department of charities. The president of the

society, Dr. Brooks H. Wells, presided and introduced the speakers. The annual election of officers resulted in the choice of the following: *President*, Dr. Walter B. Johnson, Paterson, N. J.; *Vice-President*, Dr. William Leland Stowell; *Secretary*, Dr. Charles J. Proben; *Treasurer*, Dr. Henry H. Schroeder; *Editor*, A. T. Muzzy.

The West End Medical Society.—At the annual meeting of this society, held on January 26th, the following officers were elected: *President*, Dr. Robert H. M. Dawbarn; *Vice-President*, Dr. C. G. Kerley; *Treasurer*, Dr. H. G. Myers; *Pathologist*, Dr. Walter Bensel; *Recording Secretary*, Dr. C. B. Carter; *Corresponding Secretary*, Dr. Charles Good. At the dinner toasts were responded to by Drs. Hubbard, Jelliffe, Jarman, Newcomb, Halsey, Kerley, Brockway, Ware, Dowd, Tucker, and Crandall.

The Origin of the Yellow-Fever Epidemic.—The committee of the Mississippi legislature, appointed to investigate the yellow fever of last summer, has recently made its report. It finds that the yellow fever originated at Ocean Springs, Miss., but not from the United States Marine Hospital quarantine station at Ship Island, as was supposed, and it declares that the quarantine station is in no sense a menace to the health of the Gulf coast or the South. It was generally believed that the yellow fever was introduced by Cuban refugees, who met at Ocean Springs in June to arrange for a filibustering expedition to Cuba. This theory, however, is not accepted by the committee, which asserts that the yellow fever got into this country as early as the latter part of April, and came not from Cuba, but from Guatemala. The existence of yellow fever was not recognized until September, although it had actually been present, in the belief of the committee, for five months. Although the report exonerates the Ship Island quarantine from all blame in the introduction of the disease, it nevertheless recommends its removal, as being injurious to property in the neighborhood.

Measles at Elizabeth.—The epidemic of measles, which has existed for some time at Elizabeth, N. J., is now on the wane.

The Bill to License Dispensaries.—The Sullivan bill, empowering the State board of charities to license dispensaries and placing them under the board's supervision and control, has been reported favorably to the New York State senate by the senate committee on public health. The committee amended the bill so as to permit the action of the State board of charities in refusing a license to be reviewed by the supreme court.

The Effort to Repress Public Spitting.—At a recent meeting of the Women's Health Protective Association, the president announced that she had had an important interview with Nathan Straus, the new president of the health board, who promised his hearty co-operation and the co-operation of the health board in the effort now making to enforce the law against spitting in public places. It was not made quite clear, however, in what way the rule could be enforced. The tobacco-chewing conductors might justly be called monopolists if they allowed none but themselves to defile the floors of the cars, and there are few passengers who are so public-spirited as to risk a personal altercation and insult in an effort to enforce a regulation of the board of health.

Dr. Samuel Pozzi, of Paris, author of the well-known "Treatise on Gynæcology," has recently been elected to the French senate from Dordogne.

The New York Hospital Library.—The governors of the New York Hospital have decided, it is announced, to close the library. It is not yet known what disposal will be made of it, but the books will not, so it is said, go to the library of the Academy of Medicine—which, if true, is a great pity.

The Pierce County (Washington) Medical Society met in annual session in the parlors of the Fannie Paddock Hospital, Tacoma, on January 25th. The officers chosen for the ensuing year are: *President*, Dr. H. W. Dewey; *First Vice-President*, Dr. P. B. Wing; *Second Vice-President*, Dr. C. Balabanoff; *Secretary*, Dr. C. E. Taylor; *Board of Censors*, Drs. S. H. Coleman, J. H. Yocom, and C. Quevli. The regular meetings of the society are held on the first Tuesday evening of each month.

The Church against Chewing Gum. — Bishop Vincent, of the Methodist Church, has appealed to the temperance societies in Kansas to discountenance the chewing-gum habit. He argued that the foundation of temperance reform should be laid at the chewing-gum age of childhood, as the habit was a sort of self-indulgence that should be restrained. If the child's will was educated to resist this habit, it could be more easily trained to resist other habits. The bishop was particular in his criticism of the gum-chewing girl, and drew a far from flattering portrait of her as a perpetual masticator.

The Senn Medal.—The members of the American Medical Association who intend to compete for the medal offered by Dr. Senn for the best essay on some surgical subject are requested to forward the typewritten copies of their contributions before March 1, 1898, to Dr. J. McFadden Gaston, chairman, 1½ Edgewood Avenue, Atlanta, Ga.

The Health of Gladstone.—There have of late been many disquieting rumors published in the London journals concerning the health of Mr. Gladstone. Moved by these not entirely well-founded reports, *The Lancet* publishes the following statement and asserts that its information is upon excellent authority: "Mr. Gladstone has suffered since the autumn of last year from a chronic nasal catarrh accompanied by facial neuralgia which resisted all the most careful treatment. Therefore, at Mr. Gladstone's urgent desire and because the climatic influence had previously always restored him to health, he was allowed to go to Cannes in spite of any risk attendant upon the long journey. At first the neuralgic pain almost disappeared and there were but fitful attacks. Subsequently

the presence of the mistral with cold and wet weather produced the return of the pain, but at no period has there been any evidence of increase of other inflammatory symptoms. The pain has continued since, though varying from day to day. This has doubtless had a depressing and disappointing effect upon the distinguished patient, but otherwise his general physical condition remains very much the same, and there is no further development to record."

Philadelphia's Interest in Dr. Evans' Will.—According to the will of the late Dr. Thomas W. Evans, of Paris, a large part of his fortune is to go, under certain conditions, to the city of Philadelphia for the founding of a museum and dental college. Under direction of the mayor, a petition has been filed in the common pleas court, asking for the granting of a charter in order that trustees may be appointed to take charge of the city's interest in the estate. The mayor has also asked the council for an appropriation to retain counsel in France to protect the interests of the city.

The Legal Rights and Limitations of Physicians.—It is proposed to provide free courses to physicians in Berlin, in which they shall be instructed in all the laws bearing upon the profession and its practice. According to the plan proposed, clear explanations will be given of the laws concerning accidents, insurance, judiciary functions, etc., and it is hoped thus to protect physicians from the annoyance and loss to which they are now so often exposed by reason of their ignorance of the law.

The Plague is reported to be causing terrible ravages in the interior of China, in villages on the banks of the Yangtse Kiang River.

The Title of Professor has been bestowed upon Dr. Carl Günther, the celebrated bacteriologist of Berlin, who is so popular with American physicians studying abroad.

The Red Cross in Cuba.—Miss Clara Barton, president of the American Red Cross, has gone to Havana to assist in receiving and distributing the supplies sent from this country for the relief of the destitute in the island.

Famine in Russia.—The St. Petersburg correspondent of the London *Times* reports that a failure in the harvest has caused terrible distress among the peasantry of the interior provinces, especially in central and southeastern Russia. In some places they are worse off than during the famine of 1891. In Tambov, a place to the southeast of Moscow, the peasants are feeding their half-starved cattle with the thatches of their roofs. Typhus and other diseases are making rapid headway among them.

Opposition to the Caffery Quarantine Bill.—The lower house of the Mississippi legislature has adopted a concurrent resolution, protesting against the Caffery quarantine bill and requesting the Mississippi senators and representatives "to vote for any measure that will give to the Marine Hospital service or United States authorities complete control of all external quarantine, provided our State board of health be allowed to manage and control all quarantine matters within the borders of the State."

Dr. Benjamin Lee, secretary of the Pennsylvania board of health and of the State quarantine board, has been appointed health officer of Philadelphia by Governor Hastings, to fill the vacancy caused by the resignation of Theodore Stulb.

Medical Society of the Missouri Valley.—The semiannual meeting of this society will be held at Red Oak, Iowa, Thursday, March 17, 1898.

Frauds of Frauds.—Suit has been brought recently against a number of druggists in San Francisco for selling imitations of various much-advertised pills and other patent medicines. The makers of the medicines in the East had their suspicions aroused by the fact that the stuff was sold at retail below wholesale prices, and a little investigation revealed the printer who made the spurious labels.

A Dispute over Scarlet Fever.—There have been many cases of scarlet fever recently at Fishkill Landing, and as a means of hindering the further spread of the disease the board of health ordered the Union Free School, having about eight hundred scholars, to be closed. The board of education regarded this as an entirely unnecessary precaution, and thought that the reports of the number of cases were greatly exaggerated. They protested against the action of the board of health and requested that the school be opened again, but the health officer will not consent.

The Medico-Legal Society of Philadelphia held its regular quarterly meeting on January 25th, at which there was a large attendance of physicians. The question of the purification of the water supply of Philadelphia was discussed at length, and a committee was appointed to confer with the mayor as to the best and most speedy means of effecting this much-needed improvement. It was decided to call a special meeting of the society for the evening of February 22d, to discuss the medical-charity abuse. Dr. George Mays read a paper entitled "Calomel *versus* Antitoxin." The following officers were elected for the ensuing year: *President*, Dr. J. H. Dripps; *First Vice-President*, Dr. E. B. Wheeler; *Second Vice-President*, Dr. A. M. Eaton; *Treasurer*, Dr. G. M. D. Peltz; *Secretary*, Dr. C. H. Clewell.

Examination for the Army Medical Service.—An examination of candidates for appointment to the medical corps of the United States army, to fill existing vacancies, will be held at Washington, D. C., during the month of May. Persons desiring to present themselves for examination by the board will make application to the secretary of war, before April 15, 1898, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied

by certificate based on personal acquaintance, from at least two reputable persons, as to citizenship, character, and habits. The candidate must be between twenty-two and twenty-nine years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the board. Successful candidates at the coming examination will receive a course of instruction at the next session of the Army Medical School, beginning in November, 1898. Further information regarding the examinations may be obtained by addressing Dr. George M. Sternberg, surgeon-general, United States army, Washington, D. C.

The Fifth District Branch of the New York State Medical Association will hold its fourteenth annual meeting at 315 Washington Street, Brooklyn, on Tuesday, May 24, 1898. Gonorrhœa will be the subject for discussion, and the following papers will be read: Dr. Robert W. Taylor, "Pathology and Treatment of Gonorrhœa in Males;" Dr. J. W. S. Gouley, "Urethral Strictures;" Dr. William E. Beardsley, "Gonorrhœal Rheumatism;" Dr. Lawrence Coffin, "Gonorrhœal Ophthalmia in Adults;" Dr. William McCollom, "Moral Prophylaxis and the Ethical Duty of Physicians to the Public;" Dr. J. C. Bierwirth, "The Medico-Legal Responsibility of Physicians to their Patients and Patients' Friends;" Dr. L. Grant Baldwin, "Symptoms and Diagnosis of Gonorrhœa in Females;" and Drs. Walter B. Chase and Frederick H. Wiggin, "The Palliative and Operative Treatment;" Drs. N. L. North, Jr., A. Mathewson, and L. A. W. Alleman, "Gonorrhœal Ophthalmia in Infants." Dr. N. W. Leighton is president, and Dr. E. H. Squibb secretary.

The American Laryngological, Rhinological, and Otological Society.—The southern section of this society will meet in Atlanta, Ga., Monday, March 28th, at 10 A.M., in the parlors of the Aragon Hotel. Dr. A. W. Calhoun is chairman, and Dr. Dunbar Roy is secretary.

The Indiana State Medical Society.—The next meeting of this society will be held, May 5 and 6, 1898, at Lafayette, Ind., instead of at Evansville, as previously announced.

The Mothers and Babies' Hospital.—This institution has taken the property at Lexington Avenue and Fifty-second Street for its future home. The building was originally constructed for a private hospital, and is, with some alterations now being made, well adapted to the needs of a lying-in hospital.

The American Academy of Medicine.—The twenty-third annual meeting of this society will be held at Denver, Col., on Saturday, June 4, and Monday, June 6, 1898. It is planned to hold three sessions on Saturday, beginning at 10 A.M., at 3 P.M., and at 8 P.M. Another session will be held on Monday, at 10 A.M., at which time it is hoped all the business can be completed, affording the fellows an opportunity to attend the meetings either of the Association of American Medical Colleges or the National Confederation of State Medical Examining and Licensing Boards, which meet on this day. This plan contemplates holding the reunion session on Monday evening. According to the preliminary programme just issued, seventeen papers have been promised.

Trouble Ahead for Lovers.—A reformer in the Ohio legislature has introduced a bill requiring persons applying for marriage licenses to pass a medical examination. The bill forbids the issuance of a license to any person suffering from dipsomania, insanity, or tuberculosis. It provides for a marriage examining board of three physicians in each county.

Smallpox in the South.—According to a telegram to the daily papers from Chattanooga, small-pox is spreading in that region, and it is estimated that there are one thousand cases in Northern Georgia, Tennessee, North Carolina, Southern Kentucky, and Virginia. The disease has appeared at various places in Alabama, and is causing alarm in the mining districts of east Tennessee. The State board of health of Tennessee has ordered compulsory vaccination.

The American Medico-Psychological Association.—The fifty-fourth annual meeting of the American Medico-Psychological Association will be held in St. Louis, Mo., commencing May 10, 1898, and continuing until May 13, 1898, inclusive. Arrangements have been made by the committee for the accommodation of members at the Southern Hotel, where all meetings of the association will be held.

Dr. Edgar J. Spratling, for three years last past of the Matteawan State Hospital, this State, has been appointed first assistant in the Massachusetts Hospital for Epileptics at Palmer. This institution is nearly ready for occupancy, and is expected to accommodate all the epileptics of that State, sane and insane, public and private.

Influenza in Rome.—The Rome correspondent of *The Lancet* writes that influenza is threatening to become epidemic in Rome, the number of cases having greatly increased during the first weeks in January. The disease has attacked with peculiar partiality the members of the sacred college, and very few of those now in Rome have escaped; in some, he says, the disease has declared itself with a gravity which is really alarming. Much uneasiness is felt as to the condition of Cardinals Parocchi (the vicar of Rome), Agliardi (sometime nuncio at Vienna), Oreglia (dean of the sacred college), and Mertel, who is dean by seniority, being now in his ninety-fourth year. The Pope has fortunately thus far escaped a visitation.

The Convincing Testimonial of a Savage Man.—An American consumption cure is being advertised very extensively in England, and among the numerous favorable certificates is one which states that "out of a number of cases of consumption treated therewith, only one proved unsatisfactory. The remedy has far surpassed our most sanguinary expectations."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending February 5, 1898. January 29th.—Passed Assistant Surgeon L. H. Stone ordered to be examined for retirement, February 4th, and to wait orders; Passed Assistant Surgeon B. R. Ward, upon completion of temporary duty in New York, to proceed home and await orders. January 1st.—Medical Inspector J. G. Ayers ordered to assume charge of hospital on Widow's Island, in addition to present duties; Assistant Surgeon H. H. Haas ordered to the *Vermont*. February 1st.—Surgeon A. C. H. Russell ordered to duty in the bureau of medicine and surgery, February 9th. February 4th. — Assistant Surgeon G. C. Hubbard ordered home and granted three months' sick leave.

The Late Dr. O. W. Braymer.—At a special meeting of the District Medical Society of Camden County, N. J., held January 10th, the following was adopted:

"We, the Camden District Medical Society assembled, called together by the sudden death of our esteemed associate, Dr. Orange W. Braymer, do hereby acknowledge with mingled grief and humility our childlike misapprehensions of such transitions in life.

"While yet in the full vigor of his professional manhood, and while attending the surgical needs of a suffering patient, the angel of death appeared, and very soon carried him to the bourne 'where his weary brain and tired feet will no longer brave the midnight summons, nor attend the calls of a poor suffering humanity.'

"Need we recall his manly form and earnest kindly face, or rehearse his many deeds of charity and devotion to his profession to remember him? Nay, it is well known by those who knew him best that his ill-requited devotions to his profession and his patients, his faithful friendships, and conscientious performance of all duties indicated his true nobility and reflected honor upon us, as well as upon his family, church, and State. His life is worthy of emulation, and may its impress be indelibly stamped upon our tablets of memory.

"His bereaved family, crushed by the sudden loss of an affectionate husband and father, can obtain consolation alone from that God who, as Divine Ruler of the Universe, 'knows best how to give, knows best when to take away.'

"Therefore, as a slight token of esteem and love for our dead, we hereby

"*Resolv*: That these sentiments, so well engraved upon our hearts, be recorded upon the pages of our society's history, and also transmitted to his grieving family as a memento of our sympathy; and be it further

"*Resolved*, That we attend in a body the last sad rites upon our dead brother, and bow with submission and humility to the will of God our Creator.

"O. B. Gross, M.D., J. M. Ridge, M.D., D. Benjamin, M.D., J. H. Wills, M.D., E. E. De Grofft, M.D., *Committee*."

The British Medical Association.—The sixty-sixth annual meeting of this association will be held in Edinburgh, under the presidency of Sir Thomas Grainger Stewart, on July 26th–29th. An address in medicine will be delivered by Prof. Thomas Fraser, one in surgery by Prof. Thomas Annandale, and one in psychological medicine by Sir John Batty Tuke. There will be sixteen sections, four more than before, the subjects of anatomy and physiology being assigned to separate sections, and three departments not hitherto separately formed are constituted distinct sections, namely, neurology, medicine in relation to life assurance, and tropical diseases.

Against Senate Bill No. 5.—At a meeting of the medical board of the Willard Parker and Riverside hospitals the following resolutions were adopted:

"*Whereas*, Senate bill No. 5, now before the senate committee on cities, contains radical changes in the methods now in operation, and involves material restriction in the character of the work now performed in the department of health; and

"*Whereas*, The passage of said bill would interfere with the continued progress and successful administration of the department by prohibiting the production of vaccine virus, diphtheria antitoxin, and other antitoxins, and restricting scientific research, and by limiting the work in the prevention of infectious diseases, especially tuberculosis, diphtheria, the septic diseases, and tetanus, and by removing important safeguards intended for the prevention of diphtheria, small-pox, and tuberculosis; and

"*Whereas*, The enactment of this bill would not in any respect tend to the improvement of the public health or be in the interest of the whole people of New York City; therefore be it

"*Resolved*, That this board does hereby respectfully protest against the passage of senate bill No. 5.

"*Resolved*, That these resolutions be spread upon the minutes of this board, and that copies be transmitted to the senate committee on cities, to the health board of the health department of the city of New York, and to the medical journals of this city."

Sale of Mummies in London.—Some mummies which were imported from Egypt thirty-five years ago, were sold by auction in London recently. These bodies were said to have been when alive Ptolemy II., Philadelphus, King of Egypt, Antiochus Sotee, King of Syria, and Alpina, Queen of Babylon. Ptolemy is reputed to have been the nephew of Alexander the Great, and was himself the most gifted of his line. These bodies were termed by the auctioneer "fine authentic remains," and letters testifying to their genuineness were given by Dr. Birch of the British Museum and Professor Bonomi. The whole lot sold for $375. The distinguished Ptolemy fetched a third of this sum.

Typhoid Fever is prevailing to an unusual extent in Jersey City, some forty cases having been reported in January. An investigation will be undertaken to determine the cause of the outbreak.

The American Dermatological Association.—The date of meeting of this association has been changed to May 31st, June 1st and 2d.

Reviews and Notices.

A Text-Book on the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D., Professor of Practice of Medicine and of Clinical Medicine in the Medico-Chirurgical College, Philadelphia. 8vo, pp. 1,287. Philadelphia: W. B. Saunders. 1898.

This text-book covers the ground very well, and presents a well-condensed review of a very extensive field of study. The spaces given to each subject are well-apportioned and are systematically arranged in a natural order of sequence. Departing somewhat from the standard discussion of the different diseases, the author first considers the special pathology of the affections, and then follows up with the clinical phenomena. His descriptions of these and other points are lucid and practical, and will give the student ample satisfaction. The charts of diagnosis, which are mostly arranged by the author, are well presented, and will very effectually aid in the proper analysis of leading points of difference between the diseases considered. Commendable attention is given to the bacteriological causation of diseases, and numerous illustration plates to that end are introduced in different parts of the work. Throughout the work the author has shown himself an accomplished pathologist and a practical clinician. His alleged modern methods of orthography will hardly commend themselves to the conservative portion of his readers. We have to look twice to recognize our old friend quinine, as she appears with her bobbed tail.

Practical Diagnosis: The Use of Symptoms in the Diagnosis of Disease. Second Edition. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics, Jefferson Medical College, Philadelphia. 8vo, pp. 605. Philadelphia and New York: Lea Brothers & Co. 1897.

To such as may not have become acquainted with the character of this work through its first edition, it may be proper to state that the plan followed by the author is quite different from that of similar works on the subject. Its practical value consists in making a diagnosis from leading symptoms as classified in accordance with their manifestations in the different regions of the body. This is an easy and natural method, and will serve very effectually in guiding the thought of the study in the proper directions of further investigation. The second edition, which has been thoroughly revised and considerably enlarged, is divided into two parts. The first treats of the manifestations of disease in the different organs, such as head, face, hands, arms, feet, legs, tongue, mouth, pharynx, eye, skin, thorax, abdomen, pulse, blood, bladder, and bowels, while the second part discusses the manifestations of disease by symptoms, being divided into separate chapters, as fever, headache and vertigo, coma, vomiting, cough, pain, tendon reflexes, and speech. The whole field of diagnosis is thus quite effectually covered, the preparation for its study in proper detail being given in an admirable introduction on the general principles of diagnosis. The work is well illustrated by over two hundred engravings and thirteen colored plates, the latter comprising nerve areas of skin, fever parasites, urinary crystals, and excellent representations of typical diagnostic appearances of the tongue in fevers and stomach affections.

Economics, Anæsthetics, and Antiseptics in the Practice of Midwifery. By Haydn Brown, L.R.C.P., L.R.C.S., Edinburgh. Pp. 103. London: J. and A. Churchill. 1897.

The title is the most ambitious part of this booklet, the nine chapters of which contain a series of stray thoughts, or soliloquies, without any particular cohesion. The term "economics" does not seem applicable to any of these discursive remarks, unless, perhaps, to those on the department of the lying-in chapter. We would suggest "æsthetics" as at least more euphonious. One has no fault to find with the excellent advice given in every page, but it has all been given so many times before!

It is somewhat comforting to learn that our English brethren have not found obstetrics any more profitable than we have, and that their muses have not yet attained to a state of perfection.

While the reader will run across not a few useful hints and practical suggestions in glancing through these "talks," the general impression produced is that the author has sought to relieve his own mind quite as much as to instruct the callow practitioner.

Manual of Bacteriology. By Robert Muir, M.A., M.D., F.R.C.P. Ed., and James Ritchie, M.A., M.D., B.Sc. With 108 illustrations. London: Young J. Pentland. New York: The Macmillan Company.

The series of Pentland "Student Manuals" has met with such deserved good reception that it is of interest to look over the present volume on bacteriology, which fully maintains the high standard of excellence set by its predecessors. As a work of practical utility to beginners and to practitioners of medicine it is one of the best of the smaller manuals that have come to our notice. The work is specially to be commended for its excellent *résumé* of the modern researches which have been prosecuted along etiological and hygienic lines. The clinical features in the book are also excellent, as the authors have restricted themselves to those bacteria which are productive of disease, thus making a work for the medical man rather than for the biologist.

The illustrations are for the most part from photo-micrographs and are excellent. This work, and Lehmann and Neumann's "Atlas," make an ideal combination for the student and for the practitioner.

Atlas and Essentials of Bacteriology. By Prof. K. B. Lehmann, Chief of the Hygienic Institute in Würzburg, and Dr. Rudolf Neumann, Assistant in the Hygienic Institute in Würzburg. With 63 chromolithographic plates, comprising 558 figures and numerous engravings. Wood's Medical Hand Atlases. New York: William Wood and Company. 1897.

To have Lehmann and Neumann's "Atlas" in English is a stimulus to the student and a boon to the practical worker in bacteriology. The present volume is useful to both classes of readers and also to the practitioner.

That which renders it of the greatest value is the excellent series of lithographic plates, which show in natural size and color the growth characters of a large number of organisms, both pathogenic and non-pathogenic. These show the forms of the growth upon most of the ordinary media, as gelatin, agar agar, and potato, in natural size, and also magnified pictures of individual colonies.

The text portion of the book though terse is scholarly. Our present knowledge of bacteriological subjects is briefly summarized and put in convenient shape. It is to be regretted that the systematic portion of the German edition, dealing with the descriptions of the organisms, has been omitted, as this would have been of great value to the worker interested in differential diagnosis, though of less importance to the student or practising physician.

The technical appendix is short and practical, and the directions for cultivation, staining, and animal experimentation are clear and concise.

Experimental Appendicitis. Dr. Beaussenat. Bulletin de la Société Anatomique de Paris. Pp. 155. 1897.

In a communication made to the anatomical society of Paris Dr. Beaussenat presented the results of four series of experiments on rabbits, which illustrated in an interesting manner the different anatomical types of this disease.

In the first series of attempts he produced intestinal irritation by means of indigestible foods and irritant poisons. The appendix was the site of three types of lesions:

1. Multiple ulcerations, involving the mucosa only.
2. Follicular lesions, with œdematous thickenings of the entire appendix.
3. Coincident with these follicular lesions small subperitoneal abscesses developed.

In a second series of experiments the ligation of two small vessels emanating from the appendicular artery, which ran in a semicircular manner about the appendix, was practised. As a result, a marked gangrenous appendicitis was set up, with or without perforations. In those cases in which there was no perforation, the serous layers alone remained intact.

In a third series, the blood was infected with the colon bacillus, and a trauma of the appendix produced by wounding the mucosa. After two or three months the rabbits were killed, and in three out of six rabbits experimented upon

small circular ulcers with sharply defined borders were recognizable at the site of the traumatism.

Finally, intra-appendicular injections of colon bacillus were practised. In some the small circumsessile vessels were ligated, in others not. In those cases in which the ligation had been practised, infiltration and hypertrophy, and sometimes suppuration of the lymphatics at the base of the appendix, were found, while in the series in which the ligature had been omitted no lesions appreciable by the eye were obtained.

EXERCISES IN PRACTICAL PHYSIOLOGY. By AUGUSTUS D. WALLER, M.D., F.R.S., Lecturer in Physiology to St. Mary's Hospital Medical School. Part III., Physiology of the Nervous System, Electrical Physiology. New York and London: Longmans, Green & Co. 1897.

THE present small volume, bound in cloth, gives a series of exercises and demonstrations to facilitate class-room work in practical physiology. The principal forms of electrical stimulation are carefully taken up, and the book will no doubt find a very useful place in the physiological laboratory.

A TEXT-BOOK OF SPECIAL PATHOLOGICAL ANATOMY. By ERNST ZIEGLER, Professor of Pathology in the University of Freiburg. Translated and Edited from the Eighth German Edition by DONALD MACALLISTER, M.A., M.D., Linacre Lecturer of Physic, and Tutor of St. John's College, Cambridge; and HENRY W. CATTEL, M.A., M.D., Demonstrator of Morbid Anatomy in the University of Pennsylvania. Sections IX. to XV. New York: The Macmillan Company. 1897.

WE have had occasion in a previous number of the MEDICAL RECORD (October 30th, p. 638) to speak of the earlier chapters of this very excellent translation of Ziegler's "Pathology." The appearance of Parts IX. to XV. so shortly after that of the first series is evidence of the industry of the translators.

The present sections deal with the alimentary tract, the liver and the pancreas, the respiratory system, the urinary organs, the generative organs, the eye and the ear, making a volume of six hundred and forty-two pages, which completes the translation of the original.

To offer a criticism of Ziegler's "Pathology" borders on the presumptuous; nevertheless, there are a few features that this translation brings out which are not wholly satisfactory. For instance, under the head of "Typhlitis and Perityphlitis" a very inadequate description of the lesions of appendicitis is given, and the old tale of grapestones, apple pits, and cherry pits is given, notwithstanding that repeated microscopical examinations have shown in great part the absence of the necessary histological elements in these fæcal concretions which superficially resemble such foreign bodies. No mention is made of the action of the bacillus coli communis or of its etiological relation to the disease. The chapter upon the pancreas is somewhat brief, considering the work that has been done upon this organ. In the discussion of tuberculosis of the lungs we find no mention of the importance of mixed infections, or of the etiological significance of the bodies of dead tuberculous organisms.

The translators have in several instances omitted lists of bibliographical references. While this detracts in part from the value of the book, it is a saving of space; moreover, it may be claimed that those who are able to read the references in the original could get the German edition, and thus in an English translation such lists are out of place. We believe, however, that bibliographical references constitute one of the most valuable features of a book of this type, even to a student; for a knowledge that others have done so much research often stirs him to go beyond didactic text-books into the field of actual work.

ATLAS OF CLINICAL MEDICINE. By BYROM BRAMWELL, M.D., F.R.C.P. Ed., F.R.S. Ed., Assistant Physician to the Royal Infirmary, Edinburgh. Vol. III., Part III. Edinburgh. 1897.

THE author completes his "Atlas of Clinical Medicine" with this quarto fasciele of about fifty pages and sixteen plates.

The present contribution is one of the best of the series. It includes the following original studies: "Notes on Cases of Pseudo-Hypertrophic Paralysis and Other Forms of Progressive Muscular Dystrophy" (these cases are well illustrated with photographic reproductions of the characteristic attitudes assumed in this disease, and a series of excellent photo-micrographs of the pathological findings is given); "Cyanosis and Congenital Heart Disease," with one colored plate; "Report upon Case of Calcareous Degeneration of the Heart and Arteries;" "Chlorosis;" "Pernicious Anæmia;" "Alopecia Areata," with two illustrations. In addition, three excellent lithographic reproductions of typical cases of mental disease are given. They are of acute dementia, chronic dementia, and senile dementia. A final plate of lupus vulgaris is more strikingly true to life than pleasant to look upon.

The paper and presswork are of the finest quality, and some of the plates would repay framing.

A REPORT ON THE INFLUENCE OF MILK IN SPREADING ZYMOTIC DISEASE. With a Tabular Analysis of Forty-Eight Outbreaks. By ERNEST HART, D.C.L., Editor of the *British Medical Journal*, Chairman of the Parliamentary Bills Committee of the British Medical Association. London: Smith, Elder & Co. 1897.

SO long ago as 1881 Dr. Ernest Hart read a paper on "The Influence of Milk in Spreading Zymotic Disease." He had then collected a mass of evidence which appeared to show that many of the recent epidemics were due to contaminated milk. But Dr. Hart was in advance of the times; for a short period his paper created somewhat of a sensation, but this soon passed away and people fell back into the old grooves of thought. Dr. Hart has again come forward with a new report on the same subject, and states that he has traced ninety-five fresh epidemics caused solely by milk; he even goes further than this, and says that he is positive that these are but a fraction of the total number of outbreaks caused by milk. The paper is full of interesting details, and also gives many suggested remedial measures. Now that the question of milk in relation to spread of disease is exciting universal interest, it is to be hoped that the views of Dr. Hart and of those who think with him will be received with the attention they deserve.

REPORT OF PRELIMINARY INVESTIGATIONS OF THE METABOLISM OF NITROGEN AND CARBON IN THE HUMAN ORGANISM, WITH A RESPIRATION CALORIMETER OF SPECIAL CONSTRUCTION. By W. O. ATWATER, Ph.D.; C. D. WOODS, B.S., and F. G. BENEDICT, Ph.D. Washington: United States Department of Agriculture. 1897.

PROFESSOR ATWATER'S experiments on his "Man in the Box" have achieved such a wide degree of popularity that this report of his investigations is received with interest. The studies on the problems of food supply and their economic relations here recorded were begun some years ago at Wesleyan University, and are still in progress. The present report is an introduction to the work, and considers the general problems, the methods of study, details the experiments, and gives a few conclusions.

UEBER DIE TABES. Eine Abhandlung für praktische Aerzte. Von P. J. MÖBIUS in Leipzig. Berlin: S. Karger. 1897.

THE present brochure of one hundred and thirty pages considers in short and concise form the important facts of our present-day knowledge of this disease. The chapters consider, in their order, the symptoms and course of the disease, the pathological anatomy, the etiology, the differential diagnosis, the prognosis, and the treatment. The final chapter gives an extremely instructive collection of histories illustrating the regular forms and a number of anomalous forms observed.

THE WOUNDS OF WAR, AND THE MECHANISM OF THEIR PRODUCTION AND THEIR TREATMENT. By SURGEON-COLONEL W. F. STEVENSON, A.B., M.D., M.Ch., Dublin University; Professor of Military Surgery, Army Medical School, Netley. New York, London, and Bombay: Longmans, Green & Co. 1897.

THIS is a well-printed and neatly bound octavo of four hundred and twenty pages on military surgery, past and present, which, while prepared more particularly for the surgeon in war, is so interestingly written that the civil surgeon cannot fail to find it of profit.

General considerations of the character of firearms, types of wounds, and the primary phenomena met with in gun-

shot and perforating wounds are presented in the three opening chapters. The fact that in times of war eighty-five per cent. of all deaths are due to primary hemorrhage is striking.

The author is thoroughly alive to the importance of proper aseptic and antiseptic procedures in war injuries, and expresses sanguine hopes of the outcome of some of the severer compound injuries which in the pre-Listerian days led to loss of limb and life. In chapters six, seven, and eight, gunshot wounds of the joints and long bones are described with their methods of treatment, while injuries of the head, the chest, the abdomen, and the pelvis occupy the ninth to the eleventh chapters. The concluding chapters discuss the subject of the modern small arm, and give a series of practical ideas on the methods of taking care of the wounded during actual conflict.

THE PRINCIPLES OF BACTERIOLOGY. A Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D., Professor of Hygiene and the Director of the Laboratory of Hygiene, University of Pennsylvania. Fourth Edition, Enlarged and Thoroughly Revised. Philadelphia and New York: Lea Brothers & Co. 1897.

WE have in previous numbers of the MEDICAL RECORD commented favorably on this guide to the introduction of the study of bacteria. The present volume is much larger than are its predecessors, and has been thoroughly gone over. Some new chapters have been added, the bacillus of bubonic plague is included, and the discussion of the questions of infection and immunity materially altered.

The main feature of the book's excellence is as a class book for students; for this purpose it is unexcelled.

DIE AMÖBEN, INBESONDERE VOM PARASITAREN UND CULTURELLEN STANDPUNCT. Von SANITÄTSRATH DR. ROBERT BEHLA. Berlin: August Hirschwald. 1898.

A VAST amount of investigation of the lower forms of animal life has been published by zoologists, physiologists, and physicians during the past ten years. In fact, since the appearance of Peifer's "Die Protozoen als Krankheitserreger" the field has been actively tilled.

The present brochure of seventy-five pages, illustrated with one lithographic plate, collects into convenient shape some of the important observations that have been recorded during this time. The various chapters discuss the classification of the protozoa, the amœbæ in general, the species of amœbæ, the parasitic amœbæ, the amœbæ of dysentery, and a short account of the attempts made to cultivate these organisms is given. A fairly complete list of the literature completes the contribution.

The essay presents in readable and compact form the main facts, which could be obtained otherwise only by a wide reading.

THE LIVING SUBSTANCE AS SUCH: AND AS ORGANISM. By GWENDOLIN FOULKE ANDREWS. Supplement to *Journal of Morphology*. Vol. XII., 2. Boston: Ginn & Co. 1897.

THIS essay of seventy-six pages first appeared in the *Journal of Morphology*, and is here reprinted in an attractively bound book form.

It is a thorough and painstaking study of protoplasm, as the word is used in its widest sense, and of some of the problems of the living substance as they are seen at the present day.

The writer shows a marked leaning to the views of Bütschli on the structure of protoplasm, though she is not a servile follower. To such as are interested in the general philosophical problems of the correlating of structure and function the book is heartily commended, but it is to be remarked that the path made by the present writer is by no means always a highway.

Intubation for Foreign Body.—An instance is reported by Sevestre and Bonnus (*Journ. de Méd.*) of a girl of five years who had drawn a bead into the larynx, occasioning several attacks of suffocation, one attended with abundant hæmoptysis. After a month intubation was performed, and in an attack of coughing following the introduction of as large a tube as possible, the foreign body was expelled.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 3, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

Intestinal Hydrotherapy: Methods and Uses.—DR. ROBERT COLEMAN KEMP read a paper on this subject. He said that, correctly speaking, hydrotherapy included the internal as well as the external use of water. Internal hydrotherapy was the employment of water in the intestinal tract for therapeutic purposes. Referring to the use of hot-water irrigation, the statement was made that in shock there was a vasomotor palsy, and the proper balance between the forces of inhibition and acceleration on the heart was lost. The hot injections aided (1) in restoring the proper tone of the vasomotor centres and the balance between the forces governing the heart action; (2) the heart action was also aided by the filling up of the blood-vessels; (3) the heat centres were stimulated; (4) the temperature of the blood was increased; and (5) the tone of the sweat centres was restored.

Experiments on Animals.—Dr. Kemp said that last year he had conducted a series of experiments on dogs, to determine the action of hot and cold irrigations with the double-current catheter. Each dog received about one and one-half grains of morphine, and occasionally a small quantity of ether, and a manometer was applied to one of the arteries. Then the intestine was irrigated with decinormal saline solution for ten or fifteen minutes, and the result noted. From these experiments it was learned that, if a moderate increase in the pulse tension was not objectionable, a temperature of 105° to 108° F. could be employed; but if a higher blood pressure was desired, the temperature of the fluid should be 110° to 120° F. Cold irrigations (90° to 60° F.), if kept up for twenty minutes or more, weakened the heart. The hot irrigations were excellent in shock, or before or during an operation to prevent shock, or in chloroform narcosis to prevent contraction of the vessels. Cold should be employed with caution, for idiosyncrasies to cold were more often presented than were those to heat.

In Shock from Hemorrhage.—A strong dog was bled until almost exsanguinated. The blood pressure was then found to have fallen from one hundred and fifty-five to one hundred and twelve millimetres.

Double-current irrigation with decinormal saline solution was then employed, and the temperature of the fluid gradually raised to 120° F. In ten minutes the blood pressure had risen to 140° F., and the heart was acting with fair force.

Effect on Body Temperature.—The dogs were treated as before. In some of the animals clinical thermometers were inserted in the iliac arteries, and in others in the internal carotid. Incisions were made in the axillæ, and thermometers were also inserted here. The room temperature was about 72° F., and the animals were left uncovered. Before irrigation the average axillary temperature was 99° to 99.5° F., and the temperature of the aortic blood 102.5 F. The normal blood pressure was one hundred and twenty-five to one hundred and fifty millimetres. After an interval of about fifteen minutes, irrigation was begun and kept up for twenty minutes, the temperature being increased from 110° to 120° F. It was found that the temperature of the aortic blood rose from 0.5° to 0.8°. When cold water was suddenly substituted, the temperature fell and the heart became rapid and feeble. Clinically it had been found that cold rectal irrigations were much safer than the high enemata.

Chapin had employed cold enemata in the diarrhœas of children, to reduce the temperature.

Effect on Renal Secretion.—The speaker said that, other conditions remaining the same, the secretion of the kidney was increased by a greater quantity of blood flowing through the organ. In his experiments in this direction, the animals had been treated as in the other experiments, but laparotomy had been performed and the ureters catheterized, thus excluding any chance of absorption from the intestine. The bowel was then irrigated with saline solution, the temperature being raised from 100° to 120° F. An increase in the renal secretion was noted in ten minutes, and it was very marked in twenty minutes. The pulse tension was also raised at once. If the temperature of the irrigating fluid was 100° to 102° F., the increase in the secretion did not become noticeable until after about twenty minutes. By adding a little ferrocyanide of potassium to the irrigating fluid, and testing the urine with iron as it came from the ureter, it was ascertained that in twenty minutes the urine gave the Prussian-blue reaction, no matter what the temperature of the fluid, but the higher temperatures were particularly effective in increasing the renal secretion. Small rectal enemata of saline solution and high irrigation at 100° to 104° F. increased the renal secretion without affecting the blood pressure. As cold irrigation for twenty minutes caused the animal to pass into a condition of severe shock, this method was not applicable to cases of renal insufficiency.

Hypodermoclysis.—Laparotomy was performed on a dog, and the left ureter catheterized. Five cubic centimetres of ferrocyanide of potassium was then added to three ounces of decinormal saline solution, and this mixture was injected into the tissues of the groin. In three and one-half minutes the Prussian-blue reaction was noted in the urine. Hypodermoclysis should be of value clinically in shock, in cholera, and in acute uræmic suppression to increase the secretion and to dilute the poison.

Infusion.—A dog was treated as in the last experiment, and then salt solution at a temperature of 110° F. infused slowly into the right femoral vein. In from one and one-half to two minutes the blue reaction was obtained.

Enemata.—The high enema was administered through a colon tube, and best with a fountain syringe raised about two or three feet above the patient. The colon tube should be inserted for twelve or eighteen inches, and the fluid allowed to run in slowly. The high enema was employed to relieve fæcal impaction, and also tympanites. The quantity should be one to one and one-half quarts, and the temperature 101° to 104° F. A physician in this city had told him that he had secured much better results, in exciting the renal secretion, from an enema of two ounces of salt to one and one-half quarts of hot water, than from the decinormal saline solution. It should be remembered that the colon of an infant could hold about one pint without distention, and that the adult colon held about nine pints.

Double-Current Irrigation.—In this method he preferred to use his own irrigating-tube—a tube within a tube, with the return current passing through the outer one. This tube was made of metal, hard rubber, or soft rubber, as desired. A fountain syringe was attached to the central tube. By alternately pinching the outflow tube and that of the fountain syringe, the quantity of fluid entering and escaping was easily regulated. If the return flow became clogged, the obstruction was removed by reversing the current or by the use of a small hand syringe. For diarrhœal affections the temperature of the irrigating fluid should be 101° to 105° F., and the fluid might be a weak flaxseed tea (two drachms to the quart) or have from five to fifteen minims of oil of peppermint added for each pint.

Beneficial in Dysentery and Rectal Prolapse.—Dr. William H. Thomson said that for many years he had been convinced of the fact that the reason for the great intractability of the ulcers of chronic dysentery was that the ulcer was continually bathed in foul matter. For this reason he had long been in the habit of ordering that the rectum in such cases should be washed out after every movement, with some disinfectant—preferably oil of peppermint. A long experience had taught him that it was far more effective than were other methods. All chronic inflammatory affections of the mucous membrane resulted sooner or later in a condition which was best treated by lavage. Since he had found that it was possible to practise thorough lavage of the entire colon, he had been proportionately successful in the treatment of chronic ulcerative or membranous colitis. Formerly he had dreaded these cases. He had late lytreated five such by the aid of Dr. Kemp's tube, and he had been very much impressed with the ease with which vast masses of mucus and membrane could be removed. The dislodging of these masses sometimes caused considerable pain. It was very important to remove them, because while retained they allowed the absorption of many toxins. It was the latter which gave rise to the various nervous manifestations often associated with this condition of the bowel. Of course this method of lavage could be used directly for cases of autointoxication. Every clinician occasionally observed in the course of convalescence from typhoid fever the occurrence of severe rigors, with rise of temperature. These were really pyæmic attacks, and the source of the infection was almost invariably located in the large intestine. The speaker then referred to the interesting physiological relation between the nerves of the pylorus and those of the rectum. It was for this reason, he said, that in dysentery a movement of the bowel followed the introduction of anything into the stomach, and this explained also the great emaciation observed in this disease. The therapeutic indication was clear—the application of a sedative to the rectum. He had found hot water extremely useful for this purpose. In that most depressing affection—rectal prolapse in old people—continuous hot-water irrigation of the bowel, for twenty or thirty minutes, gave most excellent results. In inflammation of the prostate or of the seminal vesicles, it was also exceedingly valuable. But the most remarkable effect of all was to be found in the influence on the renal secretion.

Allays Urethral Spasm.—Dr. Robert W. Taylor said that in that troublesome form of congestion of the prostate occurring after gonorrhœa he had found the irrigation treatment very useful. Inflammation of the prostate and seminal vesicles would be allayed by the use of hot irrigations. In some cases of gonorrhœa affecting the posterior urethra, retention of urine occurred from spasm. It was usual to treat this by hot sitz baths, but he had found it more convenient and satisfactory to use the irrigating-tube.

Promotes Absorption of Pelvic Exudates.—Dr. E. H. Grandin said that, in his hands, the method of continuous rectal irrigation had replaced the older method of vaginal irrigation in the treatment of plastic exudates, more particularly the recent ones. By this method quicker absorption was secured, probably because the hot water could be used continuously for a longer time. His custom was to place the patient in the left lateral position, or else in the dorsal position with the head lower than the buttocks. This method of continuous irrigation could be easily kept up, if necessary, for an hour or more at a time.

Useful in Acute Suppression of Urine.—It had proved extremely useful in his hands in cases of urinary toxæmia and renal insufficiency, in which the symptoms showed uræmic eclampsia to be imminent.

He knew of no method equal to irrigation of the bowel with water at a temperature of 115° to 120° F. In one case the patient had not passed water for thirty-six hours. Fifteen gallons of water at a temperature of 120° F. were used by continuous irrigation. This excited the action of the skin, the bowel, and kidneys, and the woman recovered.

Superior to Saline Infusion.—In cases of collapse from hemorrhage this irrigation treatment seemed to him superior to either infusion or injections under the skin. In cases of ectopic gestation in which rupture had occurred, he had been able to save several patients by employing continuous hot irrigation during the operation.

Non-Saline Injections are Fatal.—Dr. R. H. M. Dawbarn said that, although many patients still died from shock after major operations, little progress had been made in the treatment of this condition, and but little space was devoted to its consideration, even in the latest text-books; yet it was only along the line of prevention that we could hope to do much. In 1890, having lost a member of his family from shock after an operation, he had devoted a good deal of time to laboratory experiments on shock and its treatment by hot saline infusion. He was pleased to find that Dr. Kemp's experiments had so completely confirmed his own regarding the stimulation of the heart produced by water of a temperature of 115° to 120° F. It was during these experiments on animals that he had learned accidentally that plain water, without salt, would almost immediately kill an animal by destroying the blood corpuscles. It was for this reason that salt solution should be used.

Our Effort Should be to Prevent Shock. — Since 1891, in every severe operation in which shock was to be expected, while the patient was still under the anæsthetic, he had practised infusion of one or two litres of hot saline solution. He felt positive that in this way he had many times prevented shock. If later on there seemed to be an indication for further saline infusion, instead of reopening the vein he resorted to Dr. Kemp's method of continuous irrigation. The results had been most satisfactory. The method also had the advantage of restoring or maintaining the animal heat.

Dr. Ramon Guiteras said that in many diseased conditions of the rectum hot irrigations by the double-current tube were exceedingly beneficial. The method was of most service in cases of abscess, ulcer, and various tuberculous and syphilitic lesions. Plain water alone would sometimes produce an unpleasant dry condition of the rectum, and in these cases it was desirable to use saline solution or weak flaxseed tea. In the male these hot irrigations were chiefly useful in seminal vesiculitis, acute prostatitis following urethritis, and acute exacerbations of chronic prostatitis. By diagrams, taken from frozen sections, the speaker showed that with a Kemp tube it was possible to direct the current of hot water upon the seminal vesicles.

Dr. A. M. Phelps said that ulceration of the rectum and colon demanded treatment by continuous irrigation, together with the performance of inguinal colotomy. This had been his recent practice.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, January 27, 1898.

Simon Marx, M.D., Chairman.

Cæsarean Section for Intraligamentous Cyst Complicating Pregnancy.—Dr. Herman J. Boldt exhibited a specimen from a case in which he had done Cæsarean section for a large tumor. This tumor had more than filled the pelvis and had absolutely obstructed the parturient canal. There was an almost complete atresia of the vagina, so that the patient had first presented herself to him because of complete sterility. At the first examination the uterus seemed to be very small, and there was a small nodule alongside of this organ. He proposed to do an operation for the formation of a vagina. She went from observation for a time, and on her return it was found that the small nodule at the side of the uterus was decidedly larger. He then decided that he had to deal with a case of pregnancy, in spite of the almost microscopic size of the vaginal orifice. She went on to term, and was delivered by Cæsarean section, and at the same time of the tumor, which proved to be an intraligamentous sarcoma. The speaker said that he would invariably advocate total extirpation of the uterus instead of the Porro operation, when an operation of that kind was indicated at all. The child lived eleven days, and the mother made an uneventful recovery.

Midwives.—Dr. H. J. Garrigues read a paper with this title. He said that in 1884 a bill had been introduced into the legislature, the object of which was to give a charter to a certain institution for midwives. He had been sent, along with Dr. Warden, as a committee of the New York County Medical Society, to endeavor to kill the bill, and this they had succeeded in doing. There was no general State law, he said, for midwives, but there were two special laws affecting them—one for the city of Buffalo, and the other for Rochester. Both of these had been enacted in 1895, Buffalo being the pioneer in the movement.

Absolutely No Restrictions in New York. — In New York City any one could become a midwife, no matter what her qualifications, the law simply requiring her registration. There were at least five "schools" of midwifery in this city, where instruction was given and diplomas were issued. This astounding condition, the speaker declared, could not last forever, and if they were let alone in time a law would be enacted placing midwifery, like other branches of medicine, entirely in the hands of licensed medical practitioners.

Historical Sketch.—Dr. Garrigues said that it was not until the beginning of the seventeenth century that doctors began to attend midwifery cases, and in England physicians were not called in to normal cases of labor until the beginning of the present century. In Germany, even at the present time, physicians were not very commonly employed in ordinary cases of labor, except among a few of the well-to-do. Of the hundreds of thousands of midwives who had practised their art, only four had recorded their experience in books—three in France, and one in Germany. The practice of midwifery required special and important qualifications, for not only were two lives involved instead of one life, but knowledge of three special departments was often required—*i.e.*, internal medicine, surgery, and pædiatrics. In private practice the mortality was twice as large as in maternity hospitals, and, while the physicians were partly to blame, a large share of the responsibility belonged to the midwives. The average midwife, Dr. Garrigues averred, was entirely incapable of foreseeing complications, and, preach as one would, she could not be persuaded to practise antiseptic midwifery.

Poor Obstetricians and Inveterate Quacks.—Midwives not only did harm by being poor obstetricians, but they were notorious and inveterate quacks, and did not shrink from administering potent drugs and performing abortions. The latter evil was largely due to the fact that they were allowed to give certificates of stillbirths, and who could say that a child's death was from natural causes?

The Financial Aspect.—As it was often claimed that the chief reason for the existence of midwives was

that they would attend for a very small fee, Dr. Garrigues was at considerable pains to show from a long array of statistics that there was an abundance of physicians who would assume the care of midwifery cases for sums that the poor could afford to pay. For those too poor to pay even a small fee there was abundant provision, for, of all our numerous charities, none perhaps was so much overdone as that connected with the maternity institutions.

The Remedy.—Dr. Garrigues declared that midwives were a relic of barbaric times. Although they had never been recognized by law, they had been tolerated so long that it would be necessary, in order to do away with them, to pass a law distinctly limiting such practice to licensed physicians. It would be desirable to have such a legislative bill indorsed by this section, he said, and by the Academy of Medicine as a whole. No constitutional rights were infringed by preventing midwives from displaying signs or practising their art for a consideration; certainly this did not prevent one woman from helping another in confinement.

Educate the Midwives in Existing Institutions.—Dr. W. M. Polk said that the laity had some rights in this matter, as well as the medical profession, and that, in comparison, the physicians constituted a small minority. All that the laity wanted was educated service. It seemed to him desirable to forbid the licensing of any institution having for its object the instruction of midwives. This could be done at the schools and lying-in hospitals already in existence. He saw no reason for any one being allowed to practise midwifery without a full general medical education.

A Menace to Public Health and Morality.—Dr. T. K. Tuthill was convinced that the midwives of the present day were a menace to the public health, and while they were not abortionists, as a class, their occupation gave an opportunity for much immorality. The reputations of physicians were often endangered because of the blunders of midwives.

Midwives Should be Qualified Practitioners.—Dr. J. Henry Fruitnight said that about fourteen years ago he had read a paper, of similar tenor to that of the one just presented, before the Society of Medical Jurisprudence. He believed that the practice of midwifery, like other departments of medicine, should be limited to duly licensed practitioners. He favored the abolition of midwives.

A Strong Demand for Midwives.—Dr. N. E. Brill said that there must be a demand for midwives, or they would not exist, and hence he queried if it were practicable or desirable to attempt to put an end to a strong natural demand of this kind.

Abolish Midwives Gradually.—Dr. Robert A. Murray said that midwives existed here because foreigners coming here were accustomed to have them in their native lands. The reason they existed in the old country was that regularly qualified physicians could not be obtained at a rate within the means of these people. It was a mere question of money. He was in favor of abolishing them, but, believing that this could not be done at present, he thought it was more expedient to endeavor to restrict them, as had been done in the medical-practice act.

Midwives are Irregular Practitioners.—Dr. Malcolm McLean could see no place for an irregular practitioner of medicine in the State of New York today, and a practitioner who was capable of practising only one branch of medicine was an irregular practitioner. He would, therefore, advocate the abolition of midwives as soon as it could be easily done. It was well known that midwives arose in the East because of the division of the sexes, but such a reason no longer existed—there were female as well as male physicians.

No Legal Right and No Good Reason for their Existence.—Dr. E. H. Grandin thought the time had come when the community should realize that midwives had no right to exist—he doubted if they had any legal right, because they were not legally qualified medical practitioners. All the community could do was to amend the law so as to give this privileged class a right to "malpractise," as they now did. No midwife, with a mere smattering of knowledge of how to tie the cord, was competent to give the necessary medical supervision prior to the confinement. Moreover, there was no good reason for the existence of midwives at the present time, for many physicians would gladly accept the midwife's minimum fee, and, if even this could not be paid, there were excellent institutions for the free treatment of just such cases. Any bill presented to the legislature should have the single object of abolishing midwives.

A Blot on our Civilization.—Dr. George Tucker Harrison heartily indorsed the views expressed in the paper, believing that the midwife was an anomaly and a blot on our civilization.

Doubtful of Ability to Abolish Midwives at Present.—Dr. H. J. Boldt favored the abolition of midwives, yet doubted very much if it were possible to do this at the present time.

Midwifery Schools Now Foster Quackery.—Dr. C. A. Von Ramdohr denied that there was a single school of midwifery in the city of New York, although admitting that there were certainly so-called "schools" which were nothing but hotbeds of quackery. Midwives were recognized indirectly by boards of health. If we could prevent their registration, they would gradually die out. He was of the opinion that it was impossible to enact a law abolishing midwives, but he was equally positive that this agitation would do good.

The Midwife Belongs to the Age of the Bone Setter.—Dr. Julius Rosenberg said that he had read a paper on this subject before the New York County Medical Society, in 1893. He had pointed out that, while one-half of the confinement cases in this city came into the hands of midwives, the law did not require any evidence of qualification on the part of these midwives. Moreover, while the mortality from stillbirths in the large European cities was three per hundred, in this city it was nearly eight per hundred. A committee had been appointed to investigate the statements made in his paper. This committee had confirmed them, and had advised legislation which would suppress incompetent midwives. The matter, in accordance with the bylaws of the society, was referred to the State Medical Society, and there it ended. He believed that midwives should be absolutely abolished.

Favors Restriction and Regulation.—Dr. H. N. Vineberg said that he thought equally dark pictures could be painted regarding so-called qualified physicians as had been done for the midwives. Many of the latter received fully as good a practical training as graduates of our medical schools. While he believed midwives were a curse, as they existed at present, he thought they were nevertheless a necessity in a city like this. Their practice should, therefore, be regulated and restricted.

Favors Abolition.—Dr. H. L. Collyer also favored abolition of midwives, or, if this did not seem feasible, their restriction.

Dr. Garrigues, in closing, said that the majority seemed to favor abolition, but this could not be done in a day. The great objective point should be to prevent any more women from becoming midwives; then the practice would soon die out. Midwives were scarcely known outside of large cities having a large foreign population.

Resolution Adopted.—The following resolution was then adopted:

"*Resolved*, That the section on obstetrics and gynæcology strongly recommends taking immediate steps to secure the passage of a law providing for the supervision of all persons, not legally qualified physicians, now engaged in the practice of midwifery, and debarring from such practice all persons proving not to be competent and qualified."

Therapeutic Hints.

Impacted Fæces.—Instead of plain water for injection, use brewery yeast.—HARDEN.

In Severe Lumbago.—

℞ Ammonii chloridi ..... gr. xx.
Ammonii carbonatis ..... gr. v.
At dose in water.

Or:

℞ Ammonii chloridi ..... ʒ iij.
Liquoris hydrargyri perchloridi ..... ♏ ss.
Spiritus chloroformi ..... ♏ ss.
Infusi gentianæ compositæ ..... ad ʒ vi.
M. S. Tablespoonful ter in die ex aqua.

—R. STUART BENNIE.

Inhalation of Balsam in the Treatment of Catarrh of the upper Air Passages.—In laryngitis and catarrhal bronchitis a few drops of the following mixture are to be placed in a caraffe-shaped bottle and heated gently over the flame of a spirit lamp. When the bulb becomes filled with the vapors they are drawn by the patient through the nose by means of a tube with a flaring end.

℞ Eucalyptol ..... 0.25 cgm.
Menthol ..... 4 gm.
Terpinol ..... 2 gm.
Essence of pine ..... 1 gm.
M. S. For local use.

—KAFEMANN.

Rheumatoid Arthritis.—

℞ Colchicine ..... gr. $\frac{1}{360}$
Methyl salicylate (distilled from betula lenta) gr. iij.
For one capsule. S. Administer every hour or on alternate hours.

—ELGEOS.

A Specific for Chlorosis, according to Hayem (*La Méd. Mod.*, November 10, 1897), is the oxalate of the proto-oxide of iron, in doses of ten to twenty centigrams daily for as short a time as possible. The cure is completed by hydrotherapy, aerotherapy, and a climate of high altitude.

Tetany in Infants.—In rebellious cases the constant electric current. Relieve the gastro-intestinal derangement with:

℞ Bismuth salicylate ..... 0.30 cgm.
Benzo-naphthol ..... 0.15 cgm.
Sugar ..... q.s.
M. ft. pulv. tales No. 12. S. Take four daily.

Anthelmintics if internal worms are suspected. If the contractions persist:

℞ Potassii bromidi ..... 3 gm.
Chloralis hydratis ..... 1 gm.
Syrupi aurantii ..... 50 gm.
Aquæ destillatæ ..... 100 gm.
M. S. Three dessertspoonfuls daily.

—TORDEUS.

Neuralgia of the Ophthalmic Branch of the Trigeminus.—

℞ Neutral hydrochlorate of quinine ..... 0.10 cgm.
Hydrochlorate of morphine ..... 0.5 cgm.
Distilled water ..... 10 gm.
M. S. For external use. For instillation upon the cornea.

—MARKOV.

Alopecia Areata.—Cover the whole scalp with a one-per-cent. bichloride solution, after having made punctures over the bald area with a bunch of four needles bound together.—MARTIN.

Or make isolated punctures, especially about the periphery of the patch, with the point of a hypodermic needle dipped in:

℞ Acidi carbolici puri 3
Tincturæ cantharidis 6
Repeat every four or five days.

—PANICHI.

Massage in Chorea.—All the flexions are first to be made over the trunk and limbs, and, when the subject becomes habituated, passive movements of the limbs and of the head by gentle bending and unbending are carried out. The calming action is due to reflex effect upon the central nervous system. In chorea following infectious diseases the benefit is attributed to the exchanges being quickened, producing a more rapid neutralization of the toxins.—FEDROV, *Archives Russes de Neurologie*, No. 33, 1897.

Zona.—

℞ Menthyl salicylate ..... 4.50 gm.

To be applied upon the sound skin intervening between the plaques of eruption, and covered with oil silk and cotton to retard evaporation.—CHAMBARD-HÉNON.

Infectious Pyelonephritis.—Subcutaneous injection of saline solution in large daily quantities of two thousand grams. Within a month sixteen litres are thus administered and fourteen litres are injected per rectum. The results of the observation show that two thousand grams of saline solution can be injected daily for a number of days without danger.—BOVET *and* HUCHARD, *Journal de Médecine de Bordeaux*, November 7, 1897.

Saline Solutions, according to some recent observations of Tomasoli, should give good results in severe injury from burns. In a series of animals experimented upon, eight out of ten dogs survived under the use of two hundred grams daily of artificial serum, while those not so treated all died within two days of the injury. Two clinical observations are given to show the rapid amelioration by this method in extensive burns.—*Riforma Medica.*

Chronic Dry Myringitis.—

℞ Sozoiodic acid ..... 0.25 cgm.
Alcohol, absolute ..... 1 gm.
Castor oil ..... 10 gm.
M. S. For external use.

—STETTER.

Thiersch's Solution.—

℞ Ac. salicylici 1
Ac. borici 6
Aquæ 500
Filter.

Subcutaneous Treatment of Syphilis.—Inject each day, for one month, unless stomatitis develops, one or two cubic centimetres of the following solution:

℞ Hydrargyri benzoatis ..... 0.25 cgm.
Sodii chloridi (chemically pure),
Cocainæ hydrochloratis ..... āā 0.06 cgm.
Aquæ destillatæ ..... 30 c.c.

One cubic centimetre of this solution contains about one centigram of benzoate of mercury. Or, to assure a perfect solution of the benzoate:

℞ Hydrargyri benzoatis ..... 0.30 cgm.
Ammonii benzoatis ..... 1.50 gm.
Aquæ destillatæ ..... 30 c.c.

It is preferable to prepare the benzoate of mercury freshly rather than to use that of commerce.

—GAUCHER.

In Obstinate Atonic Diarrhœa, when simple astringent and ordinary digestive agents have failed to produce satisfactory improvement, a combination of remedies in accordance with the following prescription will usually give the desired results:

℞ Tincturæ ferri chloridi ..... ℥ ij.
Tincturæ catechu ..... ℥ iij.
Tincturæ opii camphoratæ ..... ℥ iv.
Extracti rhei aromatici fluidi ..... ℥ ij.
Spiritus vini gallici ..... ℥ ij.
Syrupi simplicis ..... q.s. ad ℥ viij.

M. S. For a child one to two years old one-half to one teaspoonful every four to six hours.

—A. L. Hall.

For Roughness of Voice.—

℞ Morphinæ muriatis,
Cocainæ hydrochloratis ..... āā 0.005
Tincturæ aconiti ..... gtt. 2
Pulveris radicis althææ 0.15
Sacchari albi ..... q.s.
M. ft. tab. No. 1. Ten such daily.

—*Medicinisch-chirurgisches Centralblatt.*

Ivy Poisoning.—None of the remedies used in the treatment of this disease is specific. All of them are designed to relieve the itching and burning and to subdue the inflammation. The following are of about equal value: (1) Saturated solution of boric acid; (2) fluid extract of grindelia robusta, one drachm to four fluid ounces of water; (3) aqueous solutions of sodium hyposulphite, one drachm to the ounce; (4) Labarraque's solution, twenty-five to fifty per cent.; (5) black wash, diluted one-half with lime water; (6) bromine, ten to fifteen minims to one ounce of olive oil.—Schonberg, *Philadelphia Polyclinic*, October 16th.

Acute Nephritis.—

℞ Diuretin ..... gr. lxxx.
Syrupi simplicis ..... ℥ v.
Aquæ destillatæ ..... ℥ v.
M. S. One tablespoonful every two hours.

—Steiner.

Tuberculosis in Children.—

℞ Balsami peruviani 5
Olei jecoris aselli 10
Gummi arabici 5
Aquæ destillatæ ..... q.s. ad emulsio 80
Syrupi aurantii corticis 20
M. S. Teaspoonful every two hours after meals.

—Schmey.

Prickly Heat.—

℞ Spiritus ætheris nitrosi ..... ℥ i.
Magnesii sulphatis ..... ℥ i.
Olei cajuputi ..... ♏ i.
Syrupi tolutani ..... ℥ ij.
Liquoris magnesii carbonatis ..... ℥ ij.
M. S. Teaspoonful thrice daily.

—Godhart *and* Starr.

Acute Coryza.—

℞ Menthol, crystals ..... ℥ iiss.
Toluol ..... gr. vss.
Alcohol, absolute ..... gtt. xi.
Liq. ferri sesquichloridi ..... gtt. vi.
M. S. Locally.

—Loeffler.

Vomiting of Pregnancy.—Cocaine hydrochlorate, one-sixth grain, by hypodermic injection once or twice a day immediately before meals; inject in the hypogastric region.—Pozzi.

Acute Mania.—

℞ Sulphonal ..... gr. xv.
Sodii bicarbonatis ..... gr. iv.
M. For one cachet. S. From one to three such cachets daily. In cases that are rebellious much larger doses are given.

—Kadt.

Hydrotherapy.—The therapeutic application of water demands at least as much care as the use of medicinal agents. Owing to the flexibility of water as a remedial agent, greater demands are made upon the practitioner than in the use of medicines. The best results may be obtained only by following an exact technique in each case. The reason that different results are obtained by different physicians from the application of water may be found in the technical errors committed on account of an erroneous conception of the *rationale* of hydrotherapy.—Simon Baruch.

Hemorrhoids of Pregnancy.—

℞ Sulphur, precipitated,
Cream of tartar ..... āā ℥ i.

—Da Costa.

Neurasthenia.—

℞ Sodii bromidi ..... ℥ i.
Liquoris potassii arsenitis ..... ℥ iss.
Extracti ergotæ ..... ℥ i.
Tincturæ opii camphoratæ ..... ℥ i.
Aquæ ..... q.s. ad ℥ iv.
M. ft. sol. S. Teaspoonful in water after meals.

—Curran Pope.

Intestinal Antiseptic.—

℞ Naphthol ..... gr. xlv.
Chloroform ..... ♏ xv.
Castor oil ..... ℥ iij.
Essence of peppermint ..... gtt. v.
M. Dose: A tablespoonful in port wine, beer, or hot and sweetened black coffee.

—De Maximovitch.

Gonorrhœa.—

℞ Oil of gaultheria ..... gr. xxx.
Bismuth subnitrate ..... ℥ x.
Vaseline, liquid ..... ℥ vi.
M. S. Inject thrice daily, after urination and retain for few seconds.

—Duquaires.

Vaginal Antisepsis.—

℞ Hydrargyri bichloridi ..... 0.30 cgm.
Acidi tartarici ..... 1 gm.
Cupri carbonatis (malachite green) ..... 0.01 cgm.
S. For one package, to dissolve in two quarts of water.

—Cassine.

Remittent Malarial Fever.—The malarial remittent fever is found most commonly in the South and Southwest; it is due to the so-called æstivo-autumnal parasite, which during the acute stage may exhibit segmentation so often (though one cycle takes several days to complete) that the fever may be intermittent or remittent, or even continued pyrexia may result from the growth of many sets of parasites, maturing at short intervals; the presence of the crescents and ovoids occurring after the first week, however, is both pathognomonic of this fever and of the æstivo-autumnal type.—Dr. Mark A. Brown (*Cincinnati Lancet-Clinic*, August 14th).

Hyperidrosis.—

℞ Bals. peruvian ..... ℥ ss.
Acidi formicici ..... ℥ ij.
Chloral. hydrat ..... ℥ ij.
Alcohol ..... ℥ v.
M. S. Apply with a cotton swab, or over large surfaces as a spray.

—Heusner.

Treatment of Gout.—You know that we inherited from Sydenham the belief that gout is made worse by red meats and that they should not be used. I have seen gouty patients in whom a single piece of ordinary red roast beef would precipitate a furious attack. I have also seen many gouty patients who would not get well until they were put upon red meat. What is the diet for gout? There is no diet for gout. It is diet for the individual. I have seen gouty patients who, if they took starch or sugars, went right down; and I have seen gouty patients who had to take starch and sugars to be built up. Therefore the first principle in the diet of gout is to adapt it to the individual

before us. You judge of the case by the effects of experiment. In a large majority of cases sugars and starches have to be cut off. In spare gouty patients starches often do good; farinaceous diet may be essential. You have to order your diet according to the individual. A milk diet is one which probably suits the large majority of patients. But that which suits the individual, the stomach, the digestion, will suit the gout or kill the gout.—H. C. Wood.

The Treatment of Blennorrhagic Conjunctivitis in the Newborn.—Everbusch (*Jour. de Méd. de Paris*, June 27, 1897) proposes painting the under side of the eyelids with lunar caustic in cases of corneal ulceration, otherwise the employment of nitrate of silver. He prescribes also several drops of a five-per-cent. solution of physostigmine three or four times daily, alternating with drops of a one-per-cent. solution of scopolamine. Every hour the following instillation should be employed:

℞ Chlorinated water..... 1 part.
Distilled water..... 2 or 3 parts.

Peroxide of Hydrogen is recommended in acute suppurative disease of the middle ear. Spray out or syringe the external meatus with warm sterile water, and, while the head is inclined to the opposite side, fill the opening with a solution of the peroxide. Then perform inflation, so that air is blown from the tympanum through the meatus.— Politzer, *Monats. für Ohrenheilk.*, May, 1897.

Cycling is a dangerous exercise for many persons. The physician should make sure of the perfect health of the individual before sanctioning it. It is usually injurious for the aged.—Mennella.

Blood Letting.—When other remedies failed, in twenty-six cases venesection restored the patient to health. The list includes puerperal fever, eclampsia, paralysis from congestion of the brain, brain fever; meningitis and cerebro-spinal meningitis; pneumonitis in its first stages; congestion of the lungs, liver, and abdominal viscera; peritonitis; croup, tonsillitis, hemorrhage of the lungs, and incipient phthisis. Repeated bleedings will do more to cure consumption in its early stages than any other single agent, especially when used in conjunction with an open-air life and in a dry and medium high atmosphere. Hoff would have every medical student instructed in the art of venesection. —Hoff.

Pertussis.—

℞ Bromoform..... 48 gtt.
Ol. amygd. dulc..... 15 gm.
Gummi arabici..... 10 "
Aq. laurocerasi..... 4 "
Aq. dest.....q.s. ad 120 "

M. S. For children under five years, as many times four drops a day as the child is old in years. From five to ten years a daily dose of twenty drops.

—Marfan.

Large Acne Pustules.—

℞ Ichthyol,
Bismuth subnitrate,
Zinc oxide.....āā 1
Vaseline..... 10

M. S. Apply at night.

—Hebra.

Thyroid Extract.—Thyroid extract has become a firmly established therapeutic agent, yet is not so generally or so fully recognized as it deserves. From year to year fresh triumphs are recorded; not only in myxœdema, but in cretinism, acromegaly, rickets, obesity, catalepsy, and ichthyosis it has scored signal success. The effects of from one to five grains of the extract are to accelerate the pulse and respiration, to increase temperature, to improve tissue metabolism, to cause a greater elimination of urea, and a more complete assimilation of nitrogenous products. There is also increased activity of the mucous membranes and skin, and the body weight is diminished, while at first there is muscular weakness. If the dose be too large there are flushings of the face, dizziness, accelerated heart action, with rise of blood pressure succeeded by a fall, nausea, vomiting, trembling of the limbs, and other toxic symptoms of more or less gravity. This toxicity depends somewhat on the preparation, fresh glands being less toxic.—W. H. Neilson.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEPUTATION TO THE WAR MINISTER ON ARMY MEDICAL REFORMS—THE MEDICAL ACTS—MR. HORSLEY AND MR. CARTER IN CONTROVERSY—THE PRESIDENT OF THE COUNCIL—THE ARCHBISHOP'S ADDRESS AT THE LONDON HOSPITAL—DR. BASTIAN—SIR F. BATEMAN — MR. HART'S SUCCESSOR — DR. JONES — PROFESSOR SIMPSON—SIR W. WADE—ROYAL INSTITUTION'S WINDFALL—THE LATE DRS. PRICHARD AND TAYLOR.

London, January 21, 1898.

Yesterday Lord Lansdowne received a deputation of the medical profession, in order to hear from it a statement as to the army medical department. The minister listened with close attention to the representations made, and professed to be entirely with the deputation in regarding the present state of things as serious. He said he was giving consideration to the subject, for there was, comparatively speaking, very little competition for vacancies in the army medical staff, and the best men did not present themselves. The deputation had urged the formation of a medical corps and the burning question of rank and titles. His lordship said he saw no objection to the formation of a corps, but it was intimately connected with the question of rank and command; he understood that the profession made no demand for command of any kind outside the corps itself. He regarded some of the present titles as extremely cumbrous, but thought it not beyond the power of the authorities to discover more suitable designations. The matter had been lately examined with care, and he hoped soon to be able to announce the conclusion of the war office. Then he asked, if the concession of the corps and titles were made, whether the authorities might rely on receiving from the profession assistance in procuring an adequate supply of the best candidates. In reply to this Dr. Farquharson, M.P., who had introduced the deputation, expressed his decided opinion that the establishment of a medical corps and the concession of titles would result in a satisfactory solution of the difficulties hitherto met with, both as to the number and qualifications of candidates. The deputation included representatives of the three kingdoms.

When two such doughty champions as Messrs. Victor Horsley and Brudenell Carter take up the gloves, we expect the play to be fast and furious. The South-west Medical Society has afforded the field for a dialectical contest of a spirited character. Mr. Horsley, as I reported, read a paper before this society on the medical acts as they are and as they ought to be. Mr. Carter soon afterward followed before the same society and traversed most of Mr. Horsley's statements. Both gentlemen had previously been at issue in the General Medical Council, and now descended into a more popular arena. Mr. Horsley is the champion of the gen-

eral practitioner and a most active medical reformer. Mr. Carter is apparently satisfied with things as they are, and defends the corporations. Both are able penmen and eloquent speakers. Both seem determined advocates. Mr. Horsley has done so much to enforce the rights of practitioners while president of the Defence Union, and is still so zealous in their cause, that he can always reckon on their sympathy. Mr. Carter's cause is unpopular. He cannot expect that the corporations for which he speaks will easily gain the affections of their alumni, whom they have estranged by long neglect. His eloquence is vain in such a cause, and he may as well throw up his brief. He seems to have been conscious of this, for he indulged in the worn-out plan of abusing plaintiff's attorney. Indeed, some of his remarks were so personal and so uncalled for that they provoked murmurs, and after his address the chairman felt called upon to explain that there was nothing in Mr. Horsley's address of a personal kind. We shall probably be treated to a further wordy warfare, waged in the larger field of the press.

Meanwhile Mr. Horsley has issued a report to registered practitioners on two points on which he objects to the action of the president of the Medical Council. One of these refers to the penal proceedings; the other to the position of foreign practitioners in England. This opposition to the president is condemned in no measured terms by Mr. Carter, as if it were a personal question. But surely an official, however highly placed, is not above criticism. It is certain official acts which Mr. Horsley calls in question, and, though there may be something to be said on both sides, it is ridiculous to maintain that opposition to such acts is a personality. The subject will undoubtedly again be discussed in the council. It is a "burning question" now in the profession, and most men seem to agree with Mr. Horsley in spite of their respect for the venerable president.

The Archbishop of Canterbury gave an address before the London Hospital Christian Association on the 11th inst. He spoke in high terms of our calling—"a glorious occupation," the study of which he thought at the head of natural science. Then he proceeded to show that there are too chief entrances of truth into the intellect and soul. One is by the bodily senses employed by the mind for investigation; the other the moral and spiritual faculty by which the mind can grasp truths which cannot be reduced to the test of experiment. Yet these truths are of the very highest importance, and both are worthy of study.

Dr. Bastian has resigned his offices at University College, but will retain the physiciancy of the Hospital for Epilepsy.

Sir Frederic Bateman, of Norwich, whose writings on "Aphasia" and the "Localization of the Faculty of Language" are so well known, has had an attack of right hemiplegia, but there were no loss of consciousness, no affection of the speech, and no impairment of intellect. It is hoped he may be able to resume his literary and professional work.

Dr. Dawson Williams, who for seventeen years has been assistant editor, succeeds Mr. Hart as editor of the association journal. The sub-editor, Mr. C. L. Taylor, takes the post of assistant editor.

Dr. Macnaughton Jones has been elected president of the Gynæcological Society for the ensuing year.

Professor Simpson is vacating the chair of forensic medicine at the University of Glasgow, on account of his declining health.

Sir Willoughby Wade is leaving Birmingham, where he has so long been a prominent figure, to settle in Italy. This step is due to the failing health of Lady Wade.

Mrs. Tyndall has handed over to the Royal Institution £1,000. This sum was left by the late professor to be thus disposed of at such time as convenient to his widow, to be used for the promotion of science.

Two veteran oculists have lately gone over to the majority. Dr. Augustin Prichard died at Clifton on the 6th inst., at the age of seventy-nine. He was formerly surgeon to the Bristol Infirmary and to the Ophthalmic Institution. He lectured on anatomy and surgery at the Medical School. He was appointed consulting surgeon when he retired from active duty at the infirmary. The other veteran alluded to was also a provincial—Robert Hibbert Taylor, formerly ophthalmologist to the Liverpool Royal Infirmary. He was deeply interested in various philanthropic institutions, especially those that ministered to the deaf and dumb. He established the first ragged school in Liverpool, and took part in many other good works. He died at the age of eighty-six.

THE PRODUCTION OF THE RASH IN EXANTHEMATOUS DISEASES.

To the Editor of the Medical Record.

Sir: In your issue of January 1st an interesting letter appears from Dr. Gage, of McCook, Neb., giving a theory as to the production of rash in any of the exanthematous diseases. His general view is that many rashes may be caused by the efforts of the skin to eliminate various poisons from the body. He has, in point of fact, reasoned out a conclusion similar to one published by myself so long ago as the year 1890, at the British Medical Association meeting at Birmingham.

Under the heading of "Internal Irritants," I have discussed a number of substances capable of setting up symptomatic skin rashes. These included (*a*) micro-organisms, (*b*) bacterial products, (*c*) certain drugs, (*d*) the virus of various diseases generated in the body, *e.g.*, gout. All these agents, I suggested, inflamed the skin as a result of direct irritation of the excretory glands. The proofs were to be found in the presence of iodine and bromine in skin lesions; in the urea to be seen on the skin surface in uræmia, and the urates in eczema of gouty origin; in the presumable infectiousness of the desquamations of many exanthems; in the toxic properties of normal sweat, demonstrated by Arloing; and lastly, in the tuberculin recently detected in the sweat of phthisis by Dr. Salter.

At the same time I pointed out that the skin was affected merely as one of a series of excretory organs, and laid down the general law that any "internal irritant" capable of causing a symptomatic rash might inflame other channels of waste exit from the body. The resulting affections I named excretory bronchitis, excretory diarrhœa, excretory nephritis, excretory pharyngitis, excretory dermatitis, and so on. I pointed out that the theory gave a rational basis to methods of treatment hitherto empirical, such as purging and sweating, and that it gave hints of therapeutic value. The theory of excretory origin is capable of very wide application; thus it explains the rash of exanthems, of antitoxin and tuberculin injection, of ptomain poisoning, of drugs, and of various phenomena, such as pruritus and phthisical night sweats.

My views have been drawn up formally in a small book, "Excretory Irritation" (Baillière & Co., London, 1897), which, I understand, has commanded some sale in the United States. As a skin specialist the subject has always presented a peculiar attraction to me personally, but its bearings are wide enough to repay careful attention on the part of the philosophical student of disease, whatever his exact position in the world of medicine.

David Walsh, M.D.

Temple, London, E. C., January 10, 1898.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 5, 1898:

	Cases.	Deaths.
Tuberculosis	173	88
Typhoid fever	9	2
Scarlet fever	105	6
Measles	312	12
Diphtheria	141	29
Laryngeal diphtheria (croup)	7	0
Chicken-pox	13	0
Cerebro-spinal meningitis	0	1
Pertussis	1	0
Erysipelas	1	0

A Novel Judicial Decision.—A Chicago boy who threw a bucket of scalding water on a shopmate during a quarrel has been offered the alternative by the judge before whom he was summoned for the offence of giving up grafts of his skin to his injured mate or going to jail pending the results of the injury. If the grafts take, the boy's life is expected to be saved, but should the man die, the water thrower must be tried for murder.—*Atlantic Med. Monthly*, December 25, 1897.

Discovery of Dwarf Races in South America.—The news has just been brought from South America of the existence of a remarkable race of pigmies in the neighborhood of the upper Amazon. A Mr. Sullivan, of Boston, has been travelling in unfrequented parts of the South American continent, and finally arrived at the headwaters of the Rio Negro, which mingles with the tributaries of the Orinoco in Guiana. Mr. Sullivan says: "I met with, while on the Rio Negro, one of the tributaries of the upper Amazon, a race of remarkably small people, who were more likely of an Indian than a negro origin, judging from their hair and the peculiar color of the skin, which was of a brilliant reddish-yellow. They are very ugly in shape. Their stomach, which is distended in the back as well as in front, is big and out of all proportion to their tiny, spindling arms and legs. From inquiry it appears, as nearly as could be ascertained, that their home was at the headwaters of the Orinoco, or else that part of Venezuela near the Brazilian border or Rio Negro watershed. These people are not over four feet eight inches in height, and the woman are less than this. They all appeared to be of the same race, and give the same location as their home." This discovery, if authentic, and there seems to be no doubt of its genuineness, should be of the greatest possible value to anthropologists. Humboldt, in the beginning of the century, recorded the tradition of a race of dwarfs inhabiting parts of South America, and stated that these pigmies were supposed to dwell in the country at the head of the Orinoco; but, as he did not visit these regions himself, concluded that the rumors were without foundation. Mr. Sullivan's observations curiously verify Humboldt's suppositions, and should go far to clear up the point as to the existence of numerous pigmy tribes in Guiana and Venezuela.

"The Lancet" on the General Practitioner in England.—*The Lancet*, in its issue of January 1st, makes some pertinent remarks on the position of the ordinary medical man in Great Britain, and says: "The general practitioner has, as a whole class, fallen, we regret to think, upon ill times. His work has grown no lighter, his responsibilities are no less exacting, but in many directions his remuneration has decreased. He is suffering in part from the overcrowding of the profession, in part from the competition of lay associations, in part from the faulty administration of certain great medical charities, and in part from the rampant prevalence of quackery, which enjoys in this era of civilization an immunity that is as perilous as it is astounding. Quacks there have been, and quacks there will ever be, but never, we believe, in the history of the world, have the mendacious statements of the charlatan enjoyed such credit or his worthless wares been bought so cheerfully and so universally at such exorbitant prices as now at the end of the nineteenth century." These words will apply with equal force, particularly as regards quackery, to the medical profession of America as to that of England *The Lancet* suggests some legislative restraint of quackery. It might be as well if a like procedure were followed here.

"Literaturitis" the Disease of Modern France.—This is a complaint an account of which will be found in no medical text-book. M. Charles Bastide is responsible for the naming of this *fin-de-siècle* disease, and in the current number of the *Fortnightly Review* discourses on its origin, its contagiousness, and on its various symptoms. It may be said that, although it is more or less prevalent in all parts of the civilized world, it is in France that its course is most virulent. The inoculation of "literaturitis" begins at an early age; the boy at school is the first to receive its baneful seeds into his system, and as he advances in years the disease gains a firmer hold, until at last the malady is past cure. In a word, the epidemic referred to is that disseminated by the corrupt literature of the day. According to M. Bastide, "Public unrest in France, the unsteadiness, the tendency to excitement, the frantic loves and hates, may be in a large measure attributable to the unwholesome pabulum France digests. Paris is the hotbed in which grow many poisonous fungi, and unfortunately Paris prepares the food and distributes it." This perhaps is scarcely a subject to be commented on in the pages of a medical journal, as it concerns the physical body only indirectly. Still there can be no doubt that the reading of pernicious literature does harmfully affect the body through the influence of the mind, especially with the young. Such books, too, tend to suggest and foster habits which, if continued in, will eventually wreck both body and mind.

Health Reports.—The following statistics concerning small-pox, cholera, and yellow fever have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended February 5, 1898:

SMALL-POX—UNITED STATES.

			Cases.	Deaths.
Alabama,	Pinckard	January 23d	Small-pox reported.	
	Selma	January 13th	1	
Tennessee,	Knoxville	January 22d	1	
Virginia,	Calhoun	February 1st	Small-pox reported.	
	Norton	February 1st	Small-pox reported.	

SMALL-POX—FOREIGN.

Bohemia,	Prague	December 26th to January 15th	35	
China,	Hong Kong	December 11th to 18th	4	3
Cuba,	Cienfuegos	January 17th to 23d	..	11
	Sagua la Grande	January 15th to 22d	47	7
England,	Southampton	January 9th to 15th	1	
India,	Calcutta	December 18th to 25th	..	1

SUGGESTIONS AS TO PROPHYLAXIS, CONTAGION, AND TREATMENT OF PNEUMONIA.[1]

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

IN no disease should a strictly routine treatment be followed less frequently than in pneumonia. Every case is, as it were, a law to itself, and much judgment is required in the management of every person thus affected. This statement is partly explained by the great difference of severity in the type of the disease according to the character of the epidemic, and also because of the variability of the constitution and powers of resistance to disease in each individual. It can be readily admitted, therefore, that, while some general plan of treatment may be well adapted in some instances to conduct the patient safely through the numerous dangers of the disease, there may be much diversity of opinion in regard to the judicious management of particular cases or special symptoms, and no systematic rules of guidance should be rigidly adhered to at all times.

It is discouraging to note, moreover, that although great progress has been made in the pathology and diagnosis of this disease, distinct advances are not readily recognized in its management. A very thorough report in regard to the treatment of pneumonia in the Massachusetts General Hospital, by Drs. Townsend and Coolidge,[1] does not show any decided improvement in its therapeusis. The death rate remains always very large and has not diminished in late years in any notable degree. There are some facts, however, which make us hopeful as to the practical outcome of future additions to our knowledge. We do not admit at present, as did older writers, that most cases in which the lung becomes rapidly consolidated are in their nature purely inflammatory. On the contrary, the local exudation of the lungs is found to be dependent upon the presence of septic germs as an efficient causative factor, and the combined symptoms of the disease rank it as an essential fever. Regarded after this manner, our treatment is more rational and in some respects very different from the one almost universally adopted a quarter of a century ago.

In a brief but suggestive paper by Dr. Henry F. Walker,[2] it is proposed to reduce the mortality of pneumonia, not by any new method for the relief of the individual case, "but rather to diminish the number of cases and thus protect the community." The idea which prevails in this writer's mind is evidently that of prophylaxis against the spread of this dread disease. How can it be effected?

Pneumonia, or lung fever, should be classed among the infectious diseases. It is disseminated by contact. It is taken by the attendants who nurse the patient and who breathe more or less constantly the contaminated air of the sick-room filled with his expired breath which is frequently the great carrier of the infection.

In order to prevent contagion, as much isolation for this disease may be required as we now enforce for scarlatina and typhus. In corroboration of these views, Dr. Walker reports two cases from his own practice within a brief period, in which pneumonia was unquestionably taken by near relatives who faithfully nursed those who were dear to them. In the instances referred to, the disease when contracted resulted fatally. The danger of taking pneumonia seems greater if the nurse is simply a relative, rather than one who by training is accustomed to sickness. "Affectionate attention and expressions of endearment" increase the danger of succumbing to the poison inhaled.

The conclusions reached from these considerations are to banish every unnecessary person from the sick-room and to warn those in charge to take needful rest and food. Change of air from time to time seems also to be required, and thus the necessity of night and day nurses becomes almost imperative. Free ventilation of the patient's room is likewise essential. No longer should rooms for pneumonia patients be close and overheated. The temperature must be moderate —65° to 68° F.—and suitable arrangements made for thorough ventilation. Unnecessary breathing of the air directly from the patient's lungs should be avoided as far as is practicable. This warning is of course more important to relatives than to nurses. Some disinfectant vaporized by boiling water may be advantageously generated in the room, both for the possible good to the patient and to prevent the spread of disease. The drug upon which I rely most for this purpose is beechwood creosote. I believe its judicious use is almost always satisfactory. Creosote is easily volatilized: it has undoubted antiseptic power; the odor of its vapors is unobjectionable, harmless, and they frequently arrest cough and bronchial irritation in a remarkable manner.

In the case of a boy, fifteen years old, who had pneumonia following grippe two years ago, I made use of these inhalations with apparent benefit. They were not used persistently, however, at that time, and inhalations such as those of benzoin, eucalyptol, and turpentine, etc., were also employed; so I am unable to affirm which remedy was most efficacious. About two weeks ago (March 3, 1894) this boy, after one week of catarrhal bronchitis of moderate severity, was suddenly taken with marked fever (102° F.) and pronounced general prostration. A warm creosote inhalation was constantly used during twenty-four hours. No cough mixture was given. Subsequently the fever disappeared, apparently owing to the influence of the inhalations upon the bronchial tract. The sputa at the time the inhalations were begun were thick, sticky, yellow, or green, although moderate in quantity. At the termination of the inhalations they were less abundant, watery in color, and less tenacious. The cough was almost gone.

In case of pneumonia following the grippe, I can affirm their useful effects in promoting the rapid resolution of the disease. I have also had some reasons to believe that they prevented the transmission of the primary affection, and it might be of the complicating

[1] Read before the Practitioners' Society of New York, January 7, 1898.

pneumonia. This view is plausible, since we know that thorough disinfection of hospital wards has arrested the spread of pneumonia, when previous to the use of disinfectants the disease showed no tendency to abatement.[3]

It is true that while inhalations have been suggested in croupous pneumonia and occasionally used, they have not hitherto been very favorably received. Thus Oertel [4] says that croupous pneumonia does not in itself offer any indication for the local application of medicinal agents in the form of either vapor or spray. He thinks the high fever and irritability of the inflamed lung contraindicate it. If these inhalations are given simply for the purpose of quieting inflammation, I am convinced from frequent experience that this object is often thus attained in a very obvious manner. But this is not all. I give them also because I believe their antiseptic power is considerable, and this indication Oertel has not apparently considered. Yet he is willing to indorse the inhalations of chloroform up to commencing narcosis in the later stages of pneumonia, when respiration is frequent and irregular, secretion suppressed, and the surface cyanosed (Sturges).[5] Leaving aside the utility of the antiseptic action of the creosote, I am satisfied that the mere inhalation of steam promotes increased secretion of the inflamed bronchial mucous membrane. Moreover, the viscid character of the sputum is thus lessened, and, expectoration being rendered easier, the dyspnœa is notably diminished. Such effects have been frequently noted by myself and others in catarrhal pneumonia,[6] and occasionally I have seen the same result in minor degree in croupous pneumonia.

In the treatment of croupous pneumonia numerous antiseptic drugs have been given internally with more or less obvious good effects.[7] The great difficulty is to give them in sufficient quantity and in a suitable manner. I claim that a sufficiently large quantity of creosote may be given by inhalation to justify its exhibition from every rational standpoint of treatment. As has been wisely said, there are other ways of estimating the value of a drug than the numerical, and a medicine may be rationally selected with which to treat disease on the ground of its ascertained physiological action, even though statistical results are not obtainable as yet in regard to the particular disease. In accord with this view, I feel further inclined to recommend creosote inhalation to my colleagues in the prophylaxis and treatment of pneumonia, on account of the influence I believe it possesses.

The following case is briefly reported to show what creosote inhalations seemingly effect:

Case of Limited Lobar Pneumonia in a Child, Apparently Much Benefited by Constant Warm Inhalations of Creosote Vapors.—G. V——, seven years of age, had had a frequent, dry cough for a week. She went to Dr. Leffert's office several times for local treatment of her throat. The cough persisted. On March 11, 1894, I saw the child. The cough continued. Nothing could be discovered in the throat or chest to account for it. There was no stomach derangement. The bowels had moved as usual in the morning. That night the child was restless, had fever, and cough was frequent and distressing; no sputa. I ordered compound tablets of ammonium chloride, one or two every hour.

March 12th, the temperature was 102 F., under the tongue; there were moist râles, a bronchial voice, and bronchial breathing at the apex of the left lung. In front and posteriorly over this region there was marked dulness. The child was confined to her bed. I ordered solution of ammonium acetate, one drachm every two hours; castor oil, two drachms; and creosote inhalation. A drachm of creosote was dissolved in an ounce of alcohol, and a teaspoonful of the solution added to a pint and a half of water in the croup kettle. Steam was to be vaporized in the room constantly, and creosote to be added from time to time.

March 13th, the same local conditions prevailed, and the same treatment was continued. Temperature, 101 F.

March 14th, compound wine of quinine, one drachm, was given every four hours; spirits of Mindererus, one drachm, every four hours, alternately with the quinine. The creosote inhalation was continued. The cough and fever continued.

March 15th, she spat up one characteristic rusty sputum, viscous and thick. The local condition at the left apex was more pronounced, but still limited to the upper lobe of the left lung.

March 16th, the temperature was normal and cough persisted. The local signs were somewhat less marked. Creosote inhalation and quinine were continued. A few tenacious but not rusty sputa were voided. Under the microscope the sputa showed diplococci pneumoniæ and an excess of fibrin. The child was allowed to sit up and be dressed. This patient had no chest pains and was quite bright during her illness; she had slight cyanosis of the face and lips for two days, and some inappetence. There was no chill at any time. The hygienic surroundings were perfect. The lungs everywhere except at the left apex were in a normal condition apparently.

To show the value of disinfection in arresting the spread of pneumonia, I would cite the facts reported by Emmerich in regard to an epidemic in a prison at Amberg. In this epidemic, in which one hundred and forty-one prisoners were attacked, one hundred and one dying of the disease, "no further cases occurred after the prison had been thoroughly disinfected and cleansed."[8] The danger of the transport of the specific microbe of pneumonia from one person to another is probably far greater in a hospital ward where there are numerous patients than it is in the case of one patient who occupies a single room and sees only his personal attendants. In any event, the use of a disinfectant like creosote is indicated. Already in the treatment of many acute catarrhal conditions of the respiratory tract, I have found antiseptic inhalations very useful in shortening their duration and preventing apparently their dissemination. It is well known that frequently when a simple cold affects one member of a family, the entire family is likely to become similarly affected. Pneumonia may not be, and probably is not, so contagious or infectious as ordinarily benign catarrhal affections are. As a more severe disease, it calls merely on this account for greater precaution in regard to prophylaxis.

If I were to be guided solely by my own observations, I should regard the risk of contagion as relatively small. Indeed, I fail to recall instances in which the transport of the contagion was unquestionable, although I have watched carefully for this accident. Yet this is no reason, in view of the proofs afforded by the observations of others, to disregard the possibility of this untoward occurrence. The collective investigation committee of the British Medical Association,[9] in one hundred replies as to the etiology of pneumonia, found nine in which the observations showed apparent transmission of the disease from one member of a family to others. In one history at least the evidence is very convincing. Zimmermann has also contributed an interesting observation illustrating the contagious character of pneumonia. In this instance the father transmitted this disease to his three children; there was here a family predisposition, which helped the transmission of the contagion due to the specific pneumococcus.[10] In the cases reported the information was given that the child first attacked

slept for two nights in the same bed with the father, who was affected with typical pneumonia. Osler in this connection states that on several occasions he has known two, three, and even four persons to be admitted to hospital from the same house. He regards pneumonia as a specific infectious disease, depending upon a micro-organism, and leads one to infer by numerous examples that he believes it to be contagious." It is probably the pythogenic form of disease, viz., the form attributable to sewer-gas emanations, in which infection is most to be met with, but not exclusively so (Powell). In the second epidemic described by Maunsel [12] in India, twenty of the attendants were attacked. Several striking instances of the apparent origin of pneumonia by contagion are quoted by Drs. Sturges[13] and Coupland from various authors. There appears to be evidence to show, therefore, that under certain circumstances not completely known pneumonia may be communicated by one person to another (Powell). Delafield [14] regards the question of the contagious nature of pneumonia for the present as an unsettled one. He thinks it is true that the disease occasionally occurs in circumscribed local epidemics, and from time to time we see several persons in one house successively attacked. On the other hand, it is well known that physicians, nurses, and relatives who take care of cases of pneumonia are not often attacked by the disease.

Drs. Sturges and Coupland, after analyzing all the evidence obtained from different sources, conclude that "there is less clincial evidence of the occurrence of pneumonia by contagion than there is of its origin from exposure, from sewer gas, from want of food, even from mental or bodily depression; and, if it be granted that any of these agents may possibly provoke pneumonia, it may be doubted whether it is further necessary, in order to satisfy the facts, to make any large appeal to this origin by contagion."

In estimating the value of the statements recorded, we must usually be in doubt as to whether, of a number of cases which occur almost simultaneously or successively within brief periods, all are due to one efficient cause acting at the same time, or have been directly communicated from patient to patient.

I would here refer to a very interesting paper by Dr. C. W. Townsend,[15] entitled "Notes on the Infectious Nature of Acute Lobar Pneumonia," in which the infection is clearly shown in many instances. "It would be safe to say that all of the houses in which two or more cases of pneumonia occurred showed some sanitary defect, due either to the faulty construction or condition of the drainage system, or to the faulty hygienic conditions of the inhabitants, or both." The testimony of Dr. Townsend was strongly corroborated by that of Dr. F. Minot, who had known lobar pneumonia to be probably caused by emanations from sewage-soaked soil in a house supposed to be in perfect sanitary condition (page 302).

On the other hand, in a case like that of Girdner's,[16] it certainly would seem as though the contagion were directly carried through the air from the patient. In this case the nurse who was attacked was competent and faithful; she constantly lifted the patient from his pillow and held a towel for him to expectorate in, thus breathing the exhalations from his lungs.

In addition to the use of antiseptic inhalations, it is also advisable as a measure of prophylaxis to disinfect thoroughly the sputa of patients affected with pneumonia; never to allow these persons to spit in their handkerchiefs or upon the floor; to prevent the sputa from becoming dry, and to direct that after the spittoons are emptied they be rendered innocuous by heat or otherwise. Indeed, the same rules are applicable as to the disinfection of the sputa of tuberculous patients. It is also indicated to disinfect the furniture, blankets, bed linen, draperies, and carpets in the bedchamber of the patient after recovery from illness, as we should do in other contagious disorders. Inas much as pneumococci are present in the mouth at the initial stage of the pneumonic invasion, it is wise to have the patient make use of antiseptic gargles. Dr. G. Lejon[1] is very strict as regards this observance, and "enjoins in every case strict buccal antisepsis, by rinsing the mouth frequently with solutions of boric acid (4 to 1,000) or of thymol (1 to 1,000). It is indicated, also, to continue the use of these antiseptic gargles even after the pneumonia is recovered from, as pneumococci may still remain in the mouth and may possibly occasion a recurrence of the pneumonia in the individual. It has been taught, indeed, by some authors that intestinal antisepsis should be attended to, as the bacteria can emigrate from the intestine to the lungs and thus cause secondary bronchopneumonia. The forcible objection to be urged against the wide dissemination of similar views is that it would produce great dread in the hearts of those who are obliged occasionally to nurse relatives ill with pneumonia because they cannot have the services of a trained nurse. This objection, it seems to me, should not be regarded as sufficiently important to militate against possible means of limiting the spread of a disease so fatal as pneumonia.

There is one other matter in connection with the question of contagion which has much interest, and it is the possibility that one may take pneumonia in part and not necessarily the whole disease. More than once I have noticed that when visiting a hospital ward where pneumonia cases were numerous I have suffered from headache and general malaise. These symptoms I have attributed, when no other sufficient cause was evident, to breathing too much of the poisonous or infective exhalations. Not only my own impression exists that certain symptoms are produced by inhaling either pneumonia, diphtheria, or other poison laden atmosphere, but the observations of other clinicians corroborate this view. Alongside of numerous morbid manifestations in the localization of the pneumococcus upon different viscera, there exist pathological affections attributable to the same micro-organism and in which there is no appreciable organic determination. These are the incomplete, rudimentary forms of the pneumococci infection. Up to the present time they can be referred only to this origin when they occur coincidently with cases of pneumonia. This fact forces one to invoke the influence of a contagion or epidemic influence." In many such cases, although the symptoms are not always similar or wholly characteristic, they are frequently distinct and apparently attributable to the presence of cases of pneumonia. So far as physicians are concerned, and why they often take, as I believe they do, abortive forms of disease and not the disease in its completeness, may be explained by the assumption and in the light of acquired knowledge that they undergo a species of preventive inoculation or acclimatization, so to speak, to the influences to which they are exposed. The long-continued inhalation or ingestion of a germ-tainted air may be considered as conferring partial immunity upon the individual from filth disease, which would readily attack and fully develop itself in one whose system had not been exposed to the acclimatizing process." Air which is contaminated by exhalations from the sick has long been known to be injurious. The organic emanations being greater from the sick than from those in health and the metamorphosis of tissue more active, pure air is essential to prevent the transport of infectious disease, as well as to facilitate recovery.[2]

We do not as yet know everything about the etiology of lobar pneumonia, and even the most searching bac-

teriological investigations do not always reveal its cause. At times the passage of the infective microbe may take place through the air immediately from the patients, or, what is almost equally possible, by means of dry sputa floating in the air just as in tuberculous phthisis. These sputa, as well as the dust of the floor of the room where the pneumonia patient is, may contain numerous pneumococci. It cannot yet be admitted, however, that one particular spore is the only means by which this disease can be produced or propagated. Pneumonia cannot always be accounted for by the reception of the specific organisms, but may possibly be regarded as some form of vasomotor (?) disturbance bringing about changes, possibly favorable to the development of ever-present germs. In considering these difficult but interesting problems, one must not confound what may be the carriers of the disease with the disease itself, or look upon what may be only epiphytes as genuine disease spores.[21] Sturges remarks that these microbes may be associated with pneumonia in an accidental rather than a causal manner; that they are epiphytes on a soil already prepared for their sustenance.[22]

Be this as it may, is it not wise to prevent the inception of the disease by a rational therapeusis, not unlike Dr. Park's as regards the prophylaxis of virulent diphtheria—viz., to use injections of solutions of boric acid for a catarrhal nose or throat in time of epidemic? One can readily see that the prophylactic treatment of pneumonia is based mainly upon its probable origin as a germ disease. Curative treatment, as already stated, has also kept in view latterly what may be accomplished by considering the microbic origin of pneumonia. It has been determined, mainly by the investigations of the Klemperer brothers,[23] Foa, Mosny, Emmerich, and Neisser, that immunity from pneumonia can be readily conferred upon animals by injections of blood serum taken after the crisis of this disease. The discovery of the antipneumotoxin makes us hope that we shall obtain the arrest of pneumonia among men during the course of its evolution. Already the Klemperers have inoculated pneumonic patients with serum taken from others after the crisis. This inoculation has led several times to the sudden reduction of temperature, which rose again only on two occasions. These experiments have been repeated by Foa and Scabia,[24] who used immunized serum from rabbits, and by Lichtheimer, who injected blood serum obtained from a man who had but recently recovered from an attack of pneumonia. In two cases thus treated there were rapid fall of temperature, slowing of the pulse, and profuse perspiration.

Charles Jansson also reports the results obtained from the treatment of ten cases of pneumonia by the injection of the serum of immunized animals. No result was obtained in one case; in three, temporary fall of temperature was observed; in five other cases, in which the temperature fell, it was ascribed to the occurrence of the crisis; in the tenth case, that of a confirmed alcoholic syphilitic, the injection was followed by a really marvellous result. The patient, who was delirious and moribund, showed a marked improvement almost at once.[25]

In all, there have been reported about thirty cases of pneumonia in human beings in which decided benefit was conferred by the injection either of serum from animals rendered immune, or of serum of convalescents from pneumonia. If these experiments in regard to the antipneumotoxin be correct, we have evidence in many of these cases of the benefit received by injections of it in the blood, and therefrom proof also of the correctness of the theory of immunity thus established.

"But it may be objected that the evidence of benefit in cases of pneumonia is equivocal, since in many untreated cases of the disease defervescence occurs early, and that little more than this was accomplished in the test cases. The regularity with which critical symptoms occurred, after a certain interval of time subsequent to the injections, seems to show, however, a direct relationship of cause and effect. The early development of the crisis is certainly unusual in cases untreated, and appears to show the influence of the injections. In any event, the injections proved harmless."[26] The injections of blood serum of persons who have passed the crisis of pneumonia may have a specially useful effect in those cases of septic pneumonia which are so fatal during any other kind of treatment, and in which the evident poisoning of the system is out of all due proportion with the localized inflammatory lesion of the lungs. Such seems to be at least the hope of Delafield.[27]

Since the foregoing was written, now some time ago, other and favorable cases of acute pneumonia treated with the antipneumonic serum have been reported. Among these I would cite particularly that of Dr. Washburn, recorded by C. J. Harnett, M.B.,[28] in which the patient, aged thirty-nine, a man of intemperate habits, was almost pulseless, with involvement of nearly the whole left lung when the first injection of antitoxin was made. From what at one time appeared to be a hopeless condition recovery took place, and it was reasonable to infer that the treatment with injections was instrumental in bringing about recovery. It would now appear without doubt from the observations of Osler[29] and others that the prognosis of pneumonia has far more to do with the grade of the toxæmia than with the mechanical interference with respiration and circulation.

The cardio-respiratory centres are unquestionably more or less intensely affected by the toxins present in this disease, and it is to their presence and action that fatal endings are most frequently due. But, as Osler sadly adds, "against it [this toxæmia] we have as yet no reliable measures at our disposal." I am not prepared at present wholly to admit this, in view of what I have written and of my later experience. In the discussion of a paper on "The Treatment of Acute Broncho-Pneumonia in Young Children," by Dr. H. D. Chapin, which I read at a meeting of the New York County Medical Society, April 26, 1897, I stated that in treatment I had for years been accustomed to keep the room full of creosote vapor in broncho-pneumonia, and to older children I also administered the drug internally. While in practice the creosote treatment seemed to have proven its value, theoretically it seemed to be indicated, for broncho-pneumonia was believed to be an infectious disease. I knew of no drug which possessed germicidal power which could be administered internally in any notable quantity except beechwood creosote. While my experience with creosote in broncho-pneumonia is limited, especially limited in young children, I still have strong faith in its value, at least in older children.[30] At the meeting referred to I presented a boy of about thirteen years who had recently recovered under the creosote treatment.[31] At the time Dr. Chapin read his paper before the New York County Medical Society, I had under my care a gentleman just convalescing from a very severe attack of grippal pneumonia. During the course of the pneumonia creosote vapor was almost constantly used for several days in the bedchamber of the patient. During a short time creosote in small repeated doses, combined with glycerin and whiskey or brandy, was given internally. My patient recovered from what I considered at one time a most threatening state. I believe the creosote treatment was of service in the management of the case. Dr. Janeway and Dr. A. H. Smith both saw this case with me in consultation. During my service last winter in St. Luke's Hospital,

several cases of pneumonia were treated partly with creosote internally and partly by inhalation. These cases, in my judgment and in that of my house staff, were favorably affected by the creosote treatment, although we could not carry it out altogether as we desired, from the fact that the patients were treated in the general ward of the hospital.

In this place, and as support to my own views of the creosote treatment of pneumonia, I would cite Dr. A. H. Kerr, of Pittsburg, Pa., who regards creosote as almost a specific in this disease. The result of two cases treated after this manner by him was read before the South Side Medical Society, November 12, 1894, and published in the *Pittsburg Medical Review*, June, 1895, page 168. In the formula employed by Dr. Kerr, one-sixty-fourth grain of strychnine and eleven minims of creosote with a little alcohol, glycerin, and water were given by the mouth every two hours. Personally, I do not believe such large doses of creosote by the mouth are desirable. Further, I am of the opinion that creosote vaporized and inhaled frequently, almost constantly for several days, is far more beneficial and essential than the same drug when it is given by the mouth.

In a very valuable paper on the "Essential Nature of Croupous Pneumonia," read at a stated meeting of the New York Academy of Medicine, December 17, 1896, Dr. Andrew H. Smith, after elaborating in detail a very attractive theory in regard to the course of the pathological process in pneumonia, says that, if his theory be sustained, "it would follow that the most natural direction for therapeutic effort would be that of attempting to render the exudate inimical to the development of the micrococci. This might be effected," writes Dr. Smith, "by acting through the blood, but better and more directly by inhalations." In order to carry out this idea practically, and in imitation of the treatment already made use of successfully by Stipp, Theodore Clemens, and others, Dr. Smith made use in one case of pneumonia of inhalations of chloroform diluted with half its bulk of alcohol. Defervescence took place on the fourth day, forty hours after the inhalations were begun. The patient was a lady, seventy-five years of age, and the pneumonia occupied the lower half of the left lung. Dr. Smith evidently believes that the germicidal power of chloroform was of value, and possibly that the hastening of the crisis was due to this action rather than to its sedative and anodyne effects, which Stipp and Clemens had in view.

One of the points in regard to the course of acute croupous pneumonia which is most important is this: to determine, if possible definitely, whether or not pneumonia has a certain well-defined course terminating in crisis on a given day, which is, so to speak, unchangeable. In other words, is pneumonia capable of jugulation? Can we abort it by any one of our known medicinal means? This question has been answered differently by different authors. Osler, for example, denies that it can. Bristow seems to be of a somewhat different opinion, since he believes that "in very mild cases all the symptoms may subside in three days, or even two days."[32] H. A. Hare feels confident that by the use of quinine, aconite, or veratrum viride, given at the stage of hyperæmia, in suitable cases, we may legitimately hope to prevent the development of the stage of consolidation. Once the latter stage has become evident, he believes there is, at present, no basis for the view that pneumonia can be aborted, or, more correctly, be shortened as to its duration, by the rational use of drugs. One thing is true, however, if we may attach faith to the experimental researches of Welch, and it is that the micrococcus lanceolatus, the admitted cause of croupous pneumonia, is a pathogenic organism, one of those least tenacious of life, and that its loss of virulence is frequent and apt to occur rapidly.[33] Is there not in this important fact a very substantial reason why we should endeavor to employ antiseptic inhalations early in the treatment of pneumonia, before lung consolidation has taken place, and while we may yet legitimately hope that the antiseptic vapor may reach every portion of the affected pulmonary area?

Of course we should expect, as in the treatment of all dangerous infectious diseases, that a certain proportion of patients will die, despite any treatment employed, no matter how rational it may be and how many lives saved may justly be ascribed to its use. This statement is true at present even of the antitoxin of diphtheria, and yet few persons to-day dispute its immense value. It may be true—it probably will be true, of any immunized serum, even the most perfect, employed later against the toxæmia of pneumonia. This affirmation is true, moreover, because the intensity of the poison of pneumonia varies, just as the susceptibility to a poison or the power of resistance to it varies in every individual. William H. Thompson expresses this thought in the following terms: "Pneumonia is too much regarded as pneumonia and nothing else, instead of being an infectious disease which produces very differing effects in those attacked, according to very varying conditions in the infection." And yet all that even Thompson has to offer us as the best available treatment of pneumonia—which he frankly admits is dealing merely with indications—is, first, to lessen vascular excitement of the early stages by aconite and sweet spirits of nitre; and later, "as much our chief task," to deal with threatened heart failure by means of equal parts of the tinctures of nux vomica, digitalis, and strophanthus, and in most extreme cases by camphor dissolved in sterilized oil and given hypodermatically.[34]

EXPERIMENTAL RABIES, WITH ESPECIAL REFERENCE TO THE BALTIMORE CITY CASES.

BY N. G. KEIRLE, A.M., M.D.,

PROFESSOR OF PATHOLOGY AND MEDICAL JURISPRUDENCE, CHIEF OF LABORATORY, PASTEUR DEPARTMENT, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.; MEDICAL EXAMINER FOR BALTIMORE, MD.

RABIES is a specific contagious neurosis, affecting markedly and peculiarly the nervous system, and capable of unlimited propagation by inoculation. The only certain proof of the existence of this disease is experimental demonstration. Preferably the inoculated material is a portion of the floor of the fourth ventricle (medulla oblongata), which is introduced subdurally by trephining rabbits. By this method the Institut Pasteur, Paris, starting with the medulla oblongata of a cow that had rabies from the bite of a rabid dog, has passed the disease from rabbit to rabbit until the four hundred and eightieth remove has been reached. Two rabbits having been trephined each time, this gives nine hundred and sixty rabbits which have taken the disease.

On October 5, 1893, I received from William R. Tatum, D.V.S., Brighton, Md., the medulla oblongata of a cow that had rabies from the bite of a rabid dog. Starting with this medulla and trephining from rabbit to rabbit, the one hundred and twenty-eighth remove has now (August, 1897) been reached. Seven hundred and thirty-one rabbits have in this way been given rabies. Using the medulla oblongata of a rabid horse, I have passed the disease from rabbit to rabbit to the tenth remove; sixty rabbits were the subjects of this experiment. Three times from the medulla oblongata of the human being I have produced the disease in rabbits. One was from a colored man who sustained a not severe bite—a slight wound over the left eye. The man was attended by Dr. William E. Magruder, of Olney, Md. His medulla oblongata was received from Dr. Tatum. Two rabbits trephined and subdurally inoculated April 19, 1894, developed rabies May 3, 1894, and died May 6, 1894. The two other victims were children, boys, aged eight years and fifteen years. They are two of the four persons who died out of eight bitten by the same dog. These cases have been designated as the Baltimore cases of rabies. On December 1, 1896, a large dog, cross between St. Bernard and mastiff, bit eight boys in Baltimore City Annex. Of these boys four died of rabies within thirty-six days after having been bitten and within nineteen days after the termination of treatment by the Pasteur method in New York. The bites were severe in character and situated on the bare face and neck.

1. Wilson, aged eleven years. Seat of bite on face over left eye. Not cauterized. Date of discharge, December 17, 1896. Date of bite, December 1, 1896. Date of first treatment, forty-two hours after bite. Date of death, January 5, 1897, eighteen days after treatment.

2. Perry, aged sixteen years. Seat of bite on cheek. No efficient cauterization. Date of discharge, December 18, 1896. Date of first treatment, seventy-seven hours after bite. Date of death, December 26, 1896, eight days after treatment.

3. Eppers, aged fifteen years. Seat of bite, back of neck. No efficient cauterization. Date of discharge, December 17, 1896. Date of first treatment, fifty hours after bite. Date of death, December 26, 1896, nine days after treatment.

4. Henry, aged eight years. Seat of bite, left cheek. No efficient cauterization. Date of discharge, December 18, 1896. Date of first treatment, seventy-seven hours after bite. Date of death, December 21, 1896, three days after treatment.

A boy named Kiel was bitten on the ear, but through an ear warmer, and therefore must be excepted from the class of bites on bare parts. All bitten on the bare face and neck died; all the others escaped. They are:

5. Perry, aged eighteen years, brother of No. 2, bitten on the arm.

6. Ashley, aged ten years, bitten on arm.

7. Buhl, aged fourteen years, bitten on arm.

8. Kiel, Joseph, aged fifteen years, bitten on ear through an ear warmer.

The foregoing is a necessary preliminary statement. The chief object of this communication is to bring before the medical profession the experimental details proving that the dog had rabies, and that two of the boys, Henry and Eppers, also had it. In the other two cases a post-mortem examination was not obtainable. Also that the virus was from the dog and not from the treatment.

The following is the post-mortem examination of the dog, December 2, 1896, 2 P.M.: Cross between St. Bernard and mastiff; yellow with white neck; weight, over one hundred pounds; shot after having bitten eight boys, chickens, and dogs. Hard palate dark bluish in color. Rigor mortis marked. Brain soft. Medulla oblongata soft, and softening around central canal of spinal cord. Lungs ooze freely bloody froth. Kidneys, dark red cortex. Bladder empty. Liver normal. Spleen normal. Stomach contains pieces of wood and stone, straw, horsehair—mane or tail. Larynx, blood in, from wounds in mouth. Trachea, blood in, from wounds in mouth. Heart normal. Lymph glands, cervical, blood effused into.

December 2, 1896, 2 P.M.: Trephined three rabbits and injected beneath the dura three minims of an emulsion of the medulla oblongata of this dog in sterilized water.

	Rabbit A.	Rabbit B.	Rabbit C.
December 8th	T. 103.5° F.	T. 103.8° F.	T. 103.4° F.
December 11th	103.7	103.9	103.8
December 14th	102.5	102.5	102.5
December 15th	103	103	104.4 (Cried out when held.)
December 16th, 2 P.M.	102.2 (Vigorous, no disorder of motility.)	103	104.3
5:20 P.M.	102.2	103	104.8
December 17th, 15th day, 2 P.M.	105.1 (Cries out and inco-ordinate; died 5 P.M.; observed to be sick 7 A.M.)	102.7 (Very active, runs about.)	103.2 (Ears erect; legs outstretched; very incoordinate.)
December 18th, 2:30 P.M.		102.8	99.2
December 19th, 17th day		103.2 (Dull but runs when incited.)	(C killed; trephined 3 rabbits, D, E, F.)
December 20th, 18th day		99.8 (Very inco-ordinate, runs about, falling over and over; died this night.)	

December 19, 1896: Killed rabbit C on seventeenth day after inoculation. Trephined and injected the emulsion of its medulla oblongata in sterilized water subdurally into rabbits D, E, and F. Amount injected, five minims.

	Rabbit D.	Rabbit E.	Rabbit F.
December 22d	(Died accidentally.)		
December 29th		T. 103.5° F.	T. 103.8° F.
December 30th		103	102.3
December 31st		103.5	102
January 1, 1897		104	103
January 2d		104	102
January 3d, 15th day		103	102
January 4th		102.2	101.6 (Dull, sluggish.)
January 5th		102.7	103.3 (More alert.)

	Rabbit E.	Rabbit F
January 6th	104	100.7 (Dull, stiff in movement.)
January 7th, 19th day	101.3 (Gritting teeth.)	97.8
January 8th	100.3 (Runs around but slips sideways.)	97.5 (Helpless on side.)
January 9th	97 (Runs around but very inco-ordinate; gritting of teeth marked.)	(Found dead on 21st day.)
January 10th	94.2 (Helpless on side; grits teeth; slight convulsions).	
January 11th	(Found dead 23d day.)	

Thus five rabbits have been given rabies from this dog; three immediately from the dog, two from one of these rabbits, this rabbit having been killed in order to stamp a suggestion of putrefaction as a fallacy. The latter experiment proves the disease to be an infectious neurosis, not a traumatic degeneration.

Experiment demonstrating that Robert Henry, aged eight years, of Baltimore, died of rabies. He underwent Pasteur treatment in New York, arriving there about December 4, 1896, and returning to Baltimore on the night of December 18, 1896, being then sick. He died of rabies, December 21, 1896, 5 P.M. He had been bitten on December 1, 1896. Post-mortem examination, December 21, 1896, 7 P.M.

December 21, 1896, 9:30 P.M.: Four rabbits were trephined and injected subdurally with emulsion in sterilized water of the medulla oblongata of the boy Henry. Amount injected, five minims.

	Rabbit G. Temp.	Rabbit H. Temp.	Rabbit I. Temp.	Rabbit J. Temp.

January 6th	97.8	96.6	102.6	102.2
January 7th, 17th day	Dead.	97.4 (Died 2 P.M.)	Found dead.	
January 8th	....	....	....	95
January 9th, 19th day	....	....	....	Found dead.

H is dull, stiff, and tremulous, with wound torn open, on the fourteenth day after trephining.

G lies flat on side, hind legs outstretched, creeping, crouching movement, on fifteenth day.

I grits teeth, stiff in movement, inco-ordinate, on fifteenth day.

J very inco-ordinate, falling over and over, on sixteenth day.

Experiments demonstrating that the boy Henry died of rabies; that the source of the virus was the dog and not the treatment; that the disease in the rabbit was a specific infection and not a traumatic degeneration (neuritis, ascending or descending).

January 7, 1897, 2 P.M.: Rabbit K trephined and subdurally inoculated from medulla oblongata of rabbit G, which died on the seventeenth day after having been trephined and subdurally inoculated from medulla oblongata of boy Henry on December 21, 1896.

		Temp. of Room	Temp. of Rabbit.
January 13, 1897, 2 P.M.,	7th day	55° F.	102° F.
January 14th, 1 P.M.,	8th day	55	103.4
January 15th, 1 P.M.,	9th day	60	102.1
January 16th, 1 P.M.,	10th day	58	102

This rabbit is pregnant, paws at floor of cage, is excited, and occasionally utters a subdued grunt. These actions are common to pregnant rabbits and may have no significance as regards rabies.

		Temp. of Room.	Temp. of Rabbit.
January 17, 1897, 1 P.M.,	11th day	58° F.	101.7° F.
January 18th, 1 P.M.,	12th day	62	101.5
January 19th, 1 P.M.,	13th day	60	101.3
January 20th, 1 P.M.,	14th day	54	101.3

Rabbit when laid on floor cannot rise, unable to get up, but when held up by the integuments of the middle of the back it can kick and strike vigorously. This is paralytic inco-ordination.

		Temp. of Room.	Temp. of Rabbit.
January 21, 1897, 1 P.M.,	15th day	66° F.	98.8° F.

Helpless on side with limbs outstretched.

		Temp. of Room.	Temp. of Rabbit.
January 22, 1897, 1 P.M.,	16th day	66° F.	96.2° F.
January 23d, 1 P.M.,	17th day	57	94.5

Can still kick feebly when held up by back.

January 24, 1897, 9:30 A.M., 18th day, found dead.

January 7, 1897, 2 P.M.: Rabbit L trephined and subdurally inoculated from medulla oblongata of rabbit G, which died on seventeenth day after having been trephined and subdurally injected from medulla oblongata of boy Henry on December 21, 1896.

		Temp. of Room.	Temp. of Rabbit.
January 13, 1897, 2 P.M.,	7th day	55° F.	102.7° F.
January 14th, 1 P.M.,	8th day	55	103.8
January 15th, 1 P.M.,	9th day	60	103.9
January 16th, 1 P.M.,	10th day	58	103.5
January 17th, 1 P.M.,	11th day	58	102.5
January 18th, 1 P.M.,	12th day	62	102.5
January 19th, 1 P.M.,	13th day	60	102.6
January 20th, 1 P.M.,	14th day	54	101.7

No coarse manifestation, but the temperature drop is significant.

		Temp. of Room.	Temp. of Rabbit.
January 21, 1897, 1 P.M.,	15th day	66° F.	100° F.

The rabbit assumes a crouched position. It is unable to sustain its body erect on pelvis and scapula. Motility of limbs impaired, hind legs almost completely paralyzed. Falls over on its sides at intervals. This crouched attitude (paralytic rabies) has been a characteristic feature of the disease in most of these rabbits.

		Temp. of Room.	Temp. of Rabbit
January 22, 1897, 2 P.M.,	16th day	66° F.	97° F.
January 23d, 1 P.M.,	17th day	57	96

Much emaciated.

January 24, 1897, 9:30 A.M., 18th day, found dead.

Experiment demonstrating that the cord of rabbit G was not virulent on the ninth day, and therefore the virus with which G was inoculated subdurally was from the dog and not from the treatment.

January 7, 1897, 2 P.M.: Rabbit M trephined and subdurally inoculated from medulla oblongata of rabbit G, which died on the seventeenth day after having been trephined and subdurally injected from medulla oblongata of boy Henry on December 21, 1896.

		Temp of Room.	Temp. of Rabbit.
January 13, 1897, 2 P.M.,	7th day	55° F.	101° F.

Somewhat off food; transferred to warm box.

		Temp. of Room.	Temp. of Rabbit
January 14, 1897, 1 P.M.,	8th day	55° F.	102° F.

Rabbit is very unwell, very thin. Sweats about muzzle. Breath fetid like gangrene. This is an intercurrent malady and has no connection whatever with rabies or with the experimental inoculation. This disease occurs not infrequently among rabbits that have been subjected to no experiment. There is reason to regard this disease as contagious, infectious. It has as a symptom diarrhœa. There is no disturbance of motility.

January 15, 1897, 9th day, found dead.

Two rabbits, O and P, trephined from this rabbit, developed no disease whatever. They were under observation for three months. This proves that this disease cannot be communicated by subdural injection of the medulla oblongata; also that the medulla oblongata did not contain the virus of rabies on the ninth day, which it would have contained had the virus been that of the treatment.

Rabbit N was subjected to the same experiments as rabbit M, and died of the same disease on the eleventh day after trephining. It is to be regretted that no experiment was made to ascertain the condition of the medulla oblongata at this date, as regards the virus of rabies.

Rabbits M and N were in the same box all the time.

Experiments demonstrating that Conrad Eppser, aged fifteen years, Baltimore, died of rabies. He underwent Pasteur treatment in New York, arriving there about December 2, 1896, and returning to Baltimore, December 17, 1896. He died of rabies, December 26, 1896, 12:5 A.M. He had been bitten on December 1, 1896. Post-mortem examination, December 26, 1896, 11 A.M.

December 26, 1896, 6 P.M.: Four rabbits were trephined and injected subdurally with emulsion in sterilized water of medulla oblongata of the boy Eppers. Amount injected, five minims. Rabbits designated by letters Q, R, S, T.

RABBIT Q.

January 5, 1897, 11th day, temperature ..... 103.3° F.
January 8th, 14th day, temperature 103.3
January 9th, 15th day, temperature 102.7
January 10th, 16th day, temperature 103.2

Does not eat. Occasional gritting of teeth at long intervals. Ears at times erect. Runs about actively. In warm pen.

January 11, 1897, 17th day, temperature ..... 97.4° F.

Excited and very inco-ordinate.

January 12, 1897, 7 A.M., 18th day, found dead.

RABBIT R.

January 8, 1897, 14th day, temperature ..... 98.4° F.
January 9th, 15th day, temperature 99
January 10th, 16th day, temperature 96

Marked paralytic rabies. Crouching, creeping, trembling inco-ordinate movement. Had been in a cool box. Transferred to warm pen.

January 11, 1897, 8:30 P.M., 17th day, temperature ..... 96° F.
January 12th, 7 A.M., 18th day, found dead.

RABBIT S.

January 8, 1897, 14th day, temperature ..... 103.2° F.
January 9th, 15th day, temperature 103

Marked paralytic rabies. Crouching, creeping movement.

January 10, 1897, 16th day, temperature (in cool box).... 95° F.
January 11th, 12 M., 17th day, found dead.

RABBIT T.

January 8, 1897, 14th day, temperature ..... 101.5° F.
January 9th, 15th day, temperature 101
January 10th, 16th day, temperature 99.9

Excited and inco-ordinate.

January 11, 1897, 17th day, temperature 99.4

Partly paralzyed. Jerking of head sideways.

January 12, 1897, 18th day, temperature 97

Aborted three fœtuses. Ears erect, legs sprawled out. Falls from side to side when it moves.

January 12, 1897, 19th day, temperature 94

Kicks and cries feebly.

January 14, 1897, 1 P.M., 20th day, found dead.

Experiments demonstrating that the boy Eppers died of rabies; that the source of the virus was the dog and not the treatment; that the disease in the rabbit is a specific infection and not a traumatic degeneration (ascending or descending neuritis).

Rabbit U trephined and subdurally injected with emulsion of medulla oblongata, that of rabbit S, which died of rabies on the seventeenth day, January 11, 1897, after having been trephined and subdurally injected from medulla oblongata of boy Eppers, who died of rabies on December 26, 1896.

January 7, 1897: In attempting to get temperature (the thermometer was introduced per anum almost its entire length) the instrument was broken inside the bowel and considerable hemorrhage resulted.

		Temp. of Room.	Temp. of Rabbit.
January 18, 1897,	1 P.M., 8th day...	62° F.	104.5° F.
January 19th,	1 P.M., 9th day...	60	102.3
January 20th,	1 P.M., 10th day...	54	102.2
January 21st,	1 P.M., 11th day...	66	101.5
January 22d,	2 P.M., 12th day...	66	101.4
January 23d,	1 P.M., 13th day...	57	98.5

Crouching, squeals, uses limbs with difficulty. Seemed dull and inactive on the twelfth day.

		Temp. of Room.	Temp. of Rabbit.
January 24, 1897,	1 P.M., 14th day...	57° F.	97.4° F.

Helpless on side.

January 25, 1897,	1 P.M., 15th day...	47	94.3

Feeble convulsive movement.

January 26, 1897, 12 M., died.

No inflammation within abdomen. No trace of the broken-off thermometer bulb could be found. This accident happened in another case and does not seem to be productive of bad results.

Rabbit V trephined and subdurally injected with emulsion of medulla oblongata of rabbit S, which died of rabies January 11, 1897, seventeenth day after having been trephined and subdurally injected from medulla oblongata of boy Eppers, who died of rabies on December 26, 1896.

		Temp. of Room.	Temp. of Rabbit.
January 17, 1897,	1 P.M., 7th day....	58° F.	105.3° F.

Rabbit has diarrhœa. It is doubtful if this rise of temperature can be attributed to incipient rabies, because it is too early.

		Temp. of Room.	Temp. of Rabbit.
January 18, 1897,	1 P.M., 8th day...	62° F.	103.8° F.
January 19th,	1 P.M., 9th day...	60	103.2
January 20th,	1 P.M., 10th day...	54	102.2
January 21st,	1 P.M., 11th day...	66	104
January 22d,	1 P.M., 12th day...	66	105.4

This elevation of temperature may be attributed to incipient rabies, but the fact that on the seventh day a like rise occurred gives room for doubt.

		Temp. of Room.	Temp. of Rabbit.
January 23, 1897,	1 P.M., 13th day...	57° F.	103.9° F.
January 24th,	1 P.M., 14th day...	57	102.3
January 25th,	1 P.M., 15th day...	47	101.7
January 26th,	5 P.M., 16th day...	47	102

Stiff in hind legs; sidelong movement.

		Temp. of Room.	Temp. of Rabbit.
January 27, 1897,	1 P.M., 17th day...	47° F.	99.4° F.

Stiff, slow, sidelong movement.

January 28, 1897,	1 P.M., 18th day...	47	95.2

Helpless on side.

January 29, 1897, 9 A.M., 19th day, found dead.

Rabbit W trephined and subdurally injected with emulsion of medulla oblongata of rabbit S, which died of rabies, January 11, 1897, seventeenth day after having been trephined and subdurally injected with medulla oblongata of boy Eppers, who died of rabies on December 26, 1896.

		Temp. of Room.	Temp. of Rabbit.
January 17, 1897.	1 P.M., 7th day...	58° F.	103.9° F.
January 18th,	1 P.M., 8th day...	62	103.6
January 19th,	1 P.M., 9th day...	60	104

January 25th,	1 P.M., 15th day...	47	102.3
January 26th,	5 P.M., 16th day...	47	99.8

Decided temperature drop. Stiff and sprawled movement of hind legs. At one time marked inco-ordinate jerking.

		Temp. of Room.	Temp. of Rabbit.
January 27, 1897.	1 P.M., 17th day...	47° F.	96.4° F.
January 28th,	9 A.M., 18th day, found dead.		

Comments and Conclusions.—If one hundred children had been bitten by this same dog in an identical manner, *i.e.*, severe and numerous bites on the bare head and neck, how many would have likewise perished? A healthy rationality will admit the probability of eighty per cent., ninety per cent., even one hundred per cent. of deaths. These cases entirely corroborate all that is claimed by statistics on this point. That is, the mortality of bites of this description is eighty per cent., ninety per cent., even one hundred per cent., when not treated by the Pasteur method. But all these were treated by this method with a result as disastrous as if they had not been treated at all. It cannot be claimed that they were not timely treated. All were under treatment in about three days after having been bitten. Greater celerity than this is only very exceptionally attainable. Pasteur institutions cannot be located within three days' journey of everywhere. The only possible explanation is that some factor difficult of appreciation caused an unusually brief incubation and speedy onset of the disease. For the completion of immunization fifteen days after the termination of treatment are required. In these cases the disease outran the remedy. If fifteen to twenty days are required for completion of the treatment and fifteen days thereafter for the completion of the immunization, then all cases which develop the disease in thirty-five days are not amenable to treatment. The stage of incubation in six per cent. is between three and eighteen days; in sixty per cent. it is between eighteen and sixty-four days. Granting the accuracy of these statistics from Bollinger in Ziemssen's "Cyclopedia of Medicine," it may be assumed that thirty-five per cent. of those bitten, or, confining the statistics to the subjects under consideration, of children at and below eighteen years of age and suffering from multiple and severe and non-cauterized bites on head and face (bare), thirty-five in one hundred cases of this description will fail to be benefited by the Pasteur treatment; sixty-five cases in one hundred cases escape when treated. Granting that twenty in one hundred would escape if not treated, then forty-five in one hundred are saved by the treatment. The foregoing remarks assume that there has been no defect in the administration of the prophylaxis. The Pasteur Institute, Paris, calls attention to the time limit, but does not plead this statute of limitation. It shows that all the deaths during treatment and at any time thereafter, from bites of the head and face, form only about six per cent. But this showing includes all ages, children and adults, and all bites, severe and slight, single and multiple. This is as inexact as the assertion attributed to John Hunter, that not more than five per cent. of all cases bitten by rabid dogs develop rabies. This may be true of slight bites through clothing, but it is entirely incorrect as regards severe multiple bites on bare parts, especially the face and neck. There are those who assert that mad-dog bites are very rare, and but very few of the few bitten develop the disease. But when they wish to impugn the Pasteur treatment they cite the present cases, asserting that fifty per cent. of the entire number bitten died of the disease, and one hundred per cent. of those bitten on the bare face and neck died. No sufficient number of cases was bitten from which to calculate percentage. They "blow hot and blow cold in the same breath," and mean nothing unless they covertly claim that the treatment produced the disease. The virus of ordinary rabies, that of the mad dog at large, the street dog, *rage de rue*, when subdurally injected into rabbits, never produces the disease before the twelfth day; rarely before the fourteenth day. On the contrary, the virus of the laboratory, the virus of the rabbit at and beyond the fiftieth remove, develops when subdurally injected into other rabbits rabies in seven or eight days. In the cases under consideration, the virus of the medulla oblongata of the boys produced rabies in the rabbit after about the same incubation as did the virus of the medulla oblongata of the street dog in question. The disease did not in any of the rabbits develop before the fourteenth day. Had the virus which gave these boys rabies been that of the laboratory, that which was used in the treatment, then the rabbits which were injected subdurally from the medulla oblongata of those rabbits which had been injected subdurally from the medulla oblongata of the boys would have developed rabies in about the seventh or eighth day. But it has been demonstrated that on the ninth day after injection the medulla oblongata was not even virulent (see rabbit G, *ante*). The use of a second series of rabbits is necessary for two purposes: First, when the virus is passed from one species to another the incubative stage is variable in the first passage. In these cases—the virus from the medulla oblongata of the boys injected subdurally into rabbits—these first rabbits might manifest the disease at some irregular period, probably a longer interval than its real incubative stage. But when the virus is passed

from the medulla oblongata of these rabbits by subdural injection into other rabbits, then these other rabbits exhibit the disease after the stage of incubation normal to the virus. The normal incubative stage of the street virus is about fifteen days. The normal incubative stage of the virus of the laboratory which is used in the treatment is about seven days. Secondly, the other purpose necessitating the use of a second series of rabbits is to exclude the effect of traumatism on the nervous system. Very rarely a case occurs after trephining, even when the virus of rabies is not used, in which after a like incubative stage the rabbit develops and dies with signs and symptoms like those of rabies. That this disease and rabies are not identical is proven by the fact that this disease cannot be given from these rabbits to a second series of rabbits by trephining and subdural injection of their medulla oblongata: still less can it be so propagated indefinitely, as is the case in rabies, which is a specific infectious neurosis. The other disease is a traumatic inflammation or degeneration. Subdural injections of guinea-pigs or rabbits with emulsion of medulla oblongata of dogs suspected to have had rabies is part of the regular routine work of institutions practising the Pasteur method. Not infrequently the dogs are thus demonstrated not to have had rabies. Patients have been treated and the dog subsequently proven not to have had rabies. If a dog under suspicious circumstances bites persons and is at once killed, it is prudent to give these persons the benefit of the doubt and treat them. They cannot safely delay until the termination of an experiment which lasts over fifteen days.

Daily throughout the world institutions administering the Pasteur treatment demonstrate that rabies is a specific infectious (contagious) neurosis, and that no other disease is capable of producing identical signs and symptoms.

ABOUT MUSHROOMS.

By HENRY G. PIFFARD, M.D.,

PROFESSOR OF DERMATOLOGY, NEW YORK UNIVERSITY.

The term mushroom is here used in a broad sense, and includes the vegetable forms commonly so called, as well as those included under the vulgar title of "toadstools;" and also the other fungi. I shall, however, exclude from present consideration the microscopic forms, and allude only to those whose size is sufficient to invite the attention of the naked eye. Many scientific men have been attracted to the study of these (from a biological standpoint) low forms of vegetable life, but the names of Fries and Cooke and Berkeley stand forth pre-eminent as regards the practical outcome of their studies. The foundations laid by these industrious men have been built upon by others, so that to-day the number of macroscopic fungi that have been carefully studied and accurately described runs into the thousands.

We are all of us acquainted with that delicious product of the pastures, the so-called "common mushroom," but there are many who are not aware that there are scores of other species that are as wholesome and as agreeable to the palate, and even more so, as the *Agaricus campester;* and it is to them that I especially ask attention.

The breadth of this subject will be appreciated when I state that Cooke has described and illustrated no less than two hundred British edible fungi, and that Mr. Charles H. Peck, State botanist, has in like manner dealt with upward of sixty species found within the limits of our own State.

The importance of the subject will be understood when we consider the information placed at our disposal by the chemists, who assure us that the mushroom from the chemical standpoint belongs to the animal rather than to the vegetable kingdom; that it possesses a much larger proportion of nitrogen than is found in any other class of vegetable life. The mushroom is essentially protein in its composition, as much so pound for pound as our ordinary butchers' meat, and hence through its economic importance it invites our careful consideration and study.

The profusion with which nature at certain seasons and times has provided such a store of nourishing food, literally to be had for the gathering, has attracted the attention of the economist from very early times. In the days of the Roman emperors mushrooms were an esteemed delicacy, and one of them, known to have been in special favor, has since received the name of *Amanita Cæsarea*, found, though not plentifully, within the borders of our own State.

The Germans, the French, and the Italians are to-day familiar with many species of wholesome fungi: and in a fresh or dried condition they constitute a not unimportant addition to the tables of rich and poor alike. Our Oriental friends in Japan and China are also fungus eaters, and several edible species are propagated artificially: and dried or otherwise prepared mushrooms from these countries are regular articles of commerce.

In England a few scientific observers and enthusiastic fungophagists have sought to spread a wider knowledge of edible fungi among the people of their country, but thus far without the full success that their efforts warrant.

Up to within a very recent period the eaters of fungi, other than the common mushroom, were few in number in America; but during the last few years they have increased so rapidly that now they can be numbered in thousands.

The great popular interest in mushrooms may be said to date from the publication in *Harper's Magazine* of a series of illustrated articles from the pen and pencil of the late Hamilton Gibson, which later were amplified into a volume entitled "Our Edible Toadstools and Mushrooms." I fancy that few can read this book without wishing that they were able to distinguish between the wholesome and the unwholesome sorts, or to be able to tell a mushroom from a "toadstool," as the vulgar would put it. Certainly this author has described the delights of the palate in such an enticing manner that one longs to search the woods and fields for the delicacies that are so charmingly described.

There is, however, another and more sombre side of the question. Many of the mushrooms are distinctly unwholesome, and some of them absolutely lethal; while concerning the greater number science is silent. In other words, there is a large number of fungi that are not positively known to be either edible or the reverse.

We may well be asked whether there is any general rule whereby the edible species can be distinguished from those that are poisonous or otherwise unwholesome. This may be promptly answered in the negative. There are many popular fallacies in this connection. Thus we have it asserted that "good" mushrooms can be distinguished from "bad" ones by cooking them with a silver spoon in the dish, and that if they are wholesome the spoon will remain untarnished, but if there be a poisonous one among the lot the silver will be blackened. This would certainly be a simple test if this were true, but unfortunately it is not. So also some declare that if the skin peels off readily from the cap the mushroom may be safely eaten, but if it is closely adherent the fungus is poisonous. This so-called rule is also untrue.

Others will state that if the gills are pinkish, as

in the *Agaricus campester*, the fungus is wholesome; while if the gills are of any other color they are poisonous. This guide is also fallacious. Certain mushrooms with white, yellow, brown, and even black gills may be eaten with safety—as, for instance, certain species appertaining to the genera Russula, Lactarius, Marasmius, Coprinus, etc., as well as some that have no gills at all, *e.g.*, certain species of Fistulina, Hydnum, Strobilomyces, Boletus, and Polyporus, which, in common with hundreds of other fungophagists, I have eaten with pleasure and without ill effects.

How, then, can we tell the wholesome from the noxious species? Can we do it by a knowledge of the genus? Unfortunately it is not so simple a matter as this. The genus Lactarius contains the wholesome *volemus* and the acrid *piperatus;* the genus Russula has the good *virescens* and the bad *emetica;* the genus Amanita holds the desirable *Cæsarea* and *rubescens*, and also the deadly poisonous *muscaria* and *phalloides;* the Boletus has the *edulis* and the *felleus;* and so with many other genera.

There are but three ways whereby one can learn to distinguish the wholesome from the vicious sorts.

In the first place, when you find an unknown mushroom take it to an expert and ask him its name and nature, and carefully note all the peculiarities of its appearance, so that when you see it again you will recognize it, just as you do the more familiar vegetables and fruits. By this means, if it is open to him, one may in a single season acquire a knowledge of a considerable number of species. No one who has once seen the Amanita *muscaria* should ever mistake it for anything else, and no one who has once seen the edible *Fistulina hepatica* or the *Strobilomyces strobilaceus* could by any possibility confound them with anything else.

Secondly, one may pursue the study of mushrooms just as one would any other branch of natural science, and carefully compare the features of any given mushroom with the detailed descriptions to be found in works of reference.

Thirdly, one may test for himself each mushroom that he encounters. In the majority of instances no harm would come from this practice, but if a person wholly unacquainted with the subject were to attempt it rashly the probabilities are that his experiments would soon be terminated. The career of the ignorant and rash experimenter would certainly be short.

During the season just passed numerous reports of mushroom poisoning have appeared in the public press, and a series of fatal cases was recently reported in the MEDICAL RECORD. The probabilities, in my opinion, are that next season's crop of poison cases will be still larger, owing to the increased interest now taken in the subject of gross mycology. In Boston there is a Mycological Society with a large membership, and this city possesses another with over one hundred members; other societies have been formed elsewhere. So far as I am aware no accidents have happened to any of the members of these societies; but many, very many other persons have undertaken the study of the subject without possessing proper facilities for obtaining accurate information concerning the various species.

At one time the idea prevailed that there were but one or two edible mushrooms, while all others, commonly called "toadstools," were noxious. Now opinion is veering too strongly to the opposite direction. Many begin to fancy that the number of injurious and poisonous mushrooms is very limited. Such is not the fact. Hay gives a list with descriptions of fifty-three species of British poisonous fungi appertaining to twenty-six genera, and this number will doubtless be greatly increased in the future, for at the present moment the effects of the majority of species of fungi on the human system are absolutely unknown.

The injurious effects of the non-edible mushrooms are not the same for every species. Some of them are simply acrid and irritating, as, for instance, the Lactarius piperatus. A fresh morsel of this fungus burns the tongue and mouth much as cayenne pepper would do. Others produce active catharsis and gastritis. In another the action is indicated by its name, to wit, the Russula *emetica*. There is, however, a fourth and much more important class, which contains a subtile poison, not producing immediate violent symptoms, but often delaying all indications of its presence for twelve or twenty-four hours. It then exerts its influence chiefly on the nervous system, and if not promptly met by an appropriate antidote frequently proves fatal. To this class belong the poisons of the Amanita *phalloides*, *verna*, and *muscaria;* and the only known antidote is the hypodermic injection of atropine. On the whole, however, our knowledge of the poisons found in some of the fungi and the symptoms they produce is very limited, and bespeaks further investigation on the part of the chemist, the physiologist, and the clinician.

There is one point, however, that should not be overlooked. Mushrooms consisting largely of protein putrefy as readily as meat does, and hence if eaten in a state of decomposition may give rise to ptomain poisoning.

The first difficulty that the student of mycology is likely to encounter is the dearth of suitable text-books and readily accessible works of reference. There is no complete compilation of the mushrooms of America, and the necessary information must be sought in divers publications. I have more than once been asked what books to read on the subject, and my experience would lead me to recommend the following. In the first place, I would advise the perusal of Gibson's work (Harper & Bros., New York, $7.50). Though not written from a strictly scientific standpoint, it is exceedingly interesting and contains a large amount of useful information. It is handsomely illustrated—too handsomely, in fact, insomuch as the different species have been delineated from the standpoint of the artist rather than from that of the accurate observer. I have no doubt that nature could produce mushrooms that resemble some of Gibson's drawings, but very much question whether it has ever done so. The next work to procure is the report of Charles H. Peck, State botanist, for 1895. To obtain it, address Mr. Melvil Dewey, secretary of the Board of Regents, Albany, N. Y., and inclose $1.35. This is a handsome quarto, with descriptive text and colored plates representing about sixty edible and four poisonous species. With these works at hand, the student is prepared to commence the systematic study of the subject, and this he may do by procuring Underwood's "Suggestions to Collectors of Fleshy Fungi," which may be obtained from the Cambridge Botanical Supply Company for twenty-five cents. This contains a synopsis of the genera belonging to the order Agaricaceæ found in the United States. For the identification of species, perhaps the most convenient work is Massee's "British Fungus Flora," imported by The Macmillan Company, New York (four volumes; price, $8). This book contains descriptions of many species not found in the United States, and omits many that are. For these latter the student may consult Peck's "Boleti of the United States," published by the University of the State of New York, and the State botanist's reports for the past fifteen or twenty years. These contain descriptions of the fungi that have been found in New York State.

Armed with the literature here mentioned, the inves-

tigator will be prepared to search the woods and fields for specimens, with confidence that he will be able to identify a considerable part of his collections and add many a dainty dish to his customary menu.

256 West Fifty-Seventh Street.

MILK POISONING OCCURRING IN INFANTS AND CHILDREN WHO HAVE BEEN FED UPON PASTEURIZED MILK—PASTEURIZED MILK AS A FOOD FOR INFANTS AND CHILDREN.[1]

By HENRY KOPLIK, M.D.,

ATTENDING PHYSICIAN TO THE GOOD SAMARITAN DISPENSARY, NEW YORK.

In his earliest experiments upon the subject of sterilization, Pasteur convinced himself beyond any question that milk could not be sterilized at the temperature applicable to wine or other fluids, 60° to 65° C. The process now called pasteurization did not apply to milk. He further established that in order completely to sterilize milk it was necessary to subject the fluid to an additional one-half atmosphere of pressure and a temperature of 110° C. In none of the writings of Pasteur do we find him advocating pasteurization, 60°–65° C., as applied to wine, as a means for the sterilization of milk. Pasteurization of milk is a process which did not obtain the sanction of the master whose name it bears. Attempts have been made by others to devise methods and apparatus for the pasteurization of milk (Thiel, Lazarus, Bitter, Russel), with varying success. Their attempts to pasteurize milk resulted in fixing a temperature at which all could agree that the germs of contagious disease which might pre-exist in the milk would be destroyed. This temperature was, after much experimentation, fixed at 75° C. (Bitter). It was also established that the milk must be kept at this temperature for a length of time, then rapidly cooled, and after cooling kept at a safe low temperature, 10 to 15° C., until ready for use. It was also agreed upon that the process of pasteurization applied only to milk for commercial use and transportation. It was meant by Bitter and Lazarus and their teacher Flügge to apply only to milk in the dairy. It was intended that by subjecting milk at the dairy, as soon as it was obtained from the animal, to the process of pasteurization, all the germs of a pathogenic nature (typhoid bacilli, cholera spirilli, diphtheria and more especially tubercle bacilli) would be destroyed. And it has been shown that the pathogenic germs of most of the known diseases would be destroyed by pasteurization. Lazarus, Bitter, Yersin, Van Geuns, distinctly proved various parts of the above proposition. Here their work stops. None of these investigators claimed that the process of pasteurization would or could be applied to the destruction of all the bacteria in the milk, nor did they attempt to apply the process of pasteurization to milk intended for infant feeding, as Freeman has done. Flügge, the teacher of two of the most successful of the above authors (Bitter and Lazarus), distinctly warns the profession against the dangers of pasteurized milk as an article of food for the infant. In other words, it is of greater importance to the infant to be guarded against the constant occurrence of milk bacteria in his food than against the occasional accidental occurrence of germs of diphtheria, typhoid fever, scarlet fever, cholera, and tuberculosis. The great mass of summer diarrhœas, the fatal gastro-intestinal disorders of infancy and early childhood, and some of the most troublesome diarrhœas of the winter months are now generally conceded to be due to bacteria and toxins in the milk food of the infant. These bacteria and toxins are not in any way destroyed or inhibited in growth by the process of pasteurization.

In the most recent work upon pasteurization, N. L. Russel claims to have succeeded in isolating fifteen different species of bacteria from pasteurized milk. The unpasteurized milk utilized by Russel for his investigations was obtained from the dairy from six to eighteen hours after milking, and contained from 25,300 to 32,800,000 of bacteria to the cubic centimetre. When pasteurized, this milk at times did not contain any bacteria; at others 57,000 bacteria to the cubic centimetre. It will thus be seen at the outset that an element of great uncertainty surrounds the process of pasteurization. Of seven samples of cream pasteurized, two were sterile, two contained 50,000 bacteria to the cubic centimetre, and this was milk and cream subjected to pasteurization six hours after milking. As a rule, Russel found that the older the milk the more bacteria it contained after pasteurization. But some of the specimens obtained from the dairy six hours after milking, and pasteurized in the laboratory, were not free from large numbers of germs. What are these germs, and how do they get into the milk? The dust in the dairy is loaded with germs of the hay and potato bacilli. Then the floor of the stalls contains food and excrementitious substances. The udder of the animal also is a great source of introduction of bacteria into the milk.

It has been demonstrated by Schultz that, even if the hands of the milkman, the stalls, and the udders of the animals are scrupulously cleaned, germs will find their way into the milk, coming from the udder of the animal directly into a sterile milking-pail. Only the milk thus obtained toward the last third of the milking-period is found to be sterile. This is found to be caused by the fact that the milk ducts of the animal's udder are at all times the harborers of germs either of disease or of decomposition: dirt from without is then introduced by the animal into its own milk ducts, and it is only after the milk has washed the ducts out thoroughly that the milk comes sterile into the milking-pail. This being so beyond the shadow of question, it can well be understood by all that germs will always exist in milk obtained even from model dairies. There will always be, even under the best hygienic public conditions, an element of the Utopian in expecting that the general public will in the near future obtain the milk from dairies equal to what are known as model dairies in the matter of cleanliness. Therefore the milk given to the vast number of our infants in large cities will be milk which, even if free from bacteria of disease like tuberculosis, diphtheria, typhoid fever, and scarlet fever, will still have a supply of bacteria indigenous to the milk, which must always be reckoned with.

These are the bacteria to be considered as etiological factors in the causation of gastro-intestinal disorders of infancy and childhood. The most deleterious of these germs are not affected by pasteurization as at present carried out. Most of the germs which thus exist in the milk, which are harmful to infants and children and which are not affected by pasteurization, divide themselves into—

(*a*) The lactic-acid-forming group.
(*b*) The butyric-acid-forming group.
(*c*) The peptonizing group of bacteria.

The first group is very active in causing gastro-intestinal disturbance, known since the publication of the learned expositions of V. Vaughan on the subject as milk poisoning. The process of sterilization at 90°–95° C. (Flügge) completely destroys these bacteria.

From milk obtained quite fresh from the dairy and pasteurized, Russel showed that, though some if not many forms were affected by pasteurization, at least three separate varieties of acid-forming bacteria could

[1] Read before the pædiatric section of the New York Academy of Medicine, December 9, 1897.

be isolated. As to the last two forms of bacteria, the peptonizing and butyric-acid forms, they are not completely destroyed by any process of sterilization at or below 100° C., but in another place I will show how their deleterious action can be minimized by certain procedures advanced by Flügge.

Not only does pasteurization leave a vast mass of bacteria in the milk, but it is the principal purpose of this paper to bring to light a certain class of cases which can be distinctly labelled as cases of milk poisoning caused by the administration of pasteurized milk to infants and children.

In the perfection of our methods of infant feeding here in America we have made the greatest strides in the art of grossly preparing the food for infant use. We can now, thanks to the energy of Professor Rotch, of Boston, give milk of any strength, accurately put together, to infants. But this is not all that is necessary. We may have the exact percentages, but if the food is not kept pure, or moderately so, and free from acids and toxins, we shall see it disagreeing with the patient.

Milk Poisoning.—I wish to define a distinct set of symptoms, which may be of an insidious nature in some cases, or marked and very troublesome in others. I have adopted Dr. Vaughan's term, "milk-poisoning," as best adapted to picture the symptomatology of the cases which are the subject of this paper. Infants or children who have taken a pasteurized milk will in many cases as a first suspicious symptom have frequent movements in the twenty-four hours. Children who have had only one movement, or a constipated movement, will suddenly have five, six, or seven loose movements. At first the movements will have a yellow, curdled, lumpy appearance and a distinct acid odor; or they will have an admixture of green and an intensely disagreeable odor. Such an infant is restless, has colicky pains, and a slight rise or no rise of temperature.

In other cases, a baby taking pasteurized milk will to all appearances be in good health and spirits, its appetite will be good, and the alvine discharges will have a normal appearance, three or four a day, when suddenly the baby will have a large number of greenish, ill-smelling movements of a very acid character, and then after a dose of oil will relapse to a normal state.

In other cases the children will have a number—one, two, or three normal movements a day; following such movements will be a large semifluid or soft movement of an extremely acid character and a distinctly penetrating sour odor. After such a movement the patient feels very weak.

Extremely interesting are the cases in which the movements are simply increased in number for that patient. They are normal in color and odor, but more fluid than they should be, and the patient does not seem to increase in weight; there may or may not be a slight temperature rise toward evening.

I had such a child under observation for fully a month, and always felt that it was the subject of poisoning and that the milk should be changed, which eventually was done.

Lastly, there are infants and children who take pasteurized milk well enough for a short time, then suddenly develop a sharp attack of gastro-enteritis which endangers their existence.

In the above I have kept before my eyes only those cases which have come under my observation. In one case the milk was prepared by the best and most widely used laboratory for feeding infants in private practice. The other cases were innumerable cases in which was given pasteurized milk from a well-known leading charity, or pasteurized milk from the laboratory connected with my service at the Good Samaritan Dispensary. In the latter cases the Freeman pasteurizer was used, the milk rapidly cooled, and then kept on ice, and the patients were warned to keep it on ice at home.

Subacute Milk Poisoning Caused by Pasteurized Milk, November, 1896.—A boy, five years of age, weighing forty-one pounds, only child of healthy parents, brought up in infancy on sterilized milk. The child was well up to about a year ago, when, it may be mentioned, the sterilization of the milk in his food was omitted. He then suffered occasionally from a diarrhœa: the diarrhœa consisted of five or six profuse movements, which would weaken the boy. After dieting in various ways the patient recovered. The boy remained well during the past summer in the mountains, but at intervals suffered from a slight looseness of the bowels. He gained in weight. During the past five weeks he began to have two or more diarrhœal movements daily. Diet during this time contained among other things, as a principal or exclusive element, pasteurized milk. No fever curve.

Status: A well-nourished boy; tongue clean; no pyrexia even in the evening; the skin elsewhere showed a very few varicella spots of quite recent maturation; no enlarged spleen or mesenteric glands or lymph nodes. The patient once a day would have a very large normal movement, and at night a profuse watery movement of yellow color: this had a very sour odor, which penetrated the room. After such a movement the patient was weak, though he insisted that he should play around the house. No pyrexia. At this time the boy was, and had been for a period of two weeks, on an exclusively milk diet. The family being well-to-do, the milk was obtained and modified at the best laboratory in town, on the Rotch plan. The ingredients of the milk were constantly changed by the attending physician, who argued that there was a neurotic intestinal diarrhœa. A consultation with a noted pædiatrist before I was called in led to the supposition that there was an irritant of some kind in the gut, and high injections were advised. The milk during all this time was pasteurized, and was the exclusive diet. After a close study of the case, having in my mind placed it with others of the same kind I had seen before, I pronounced it one of milk poisoning, pure and simple, in a very susceptible subject. I observed the lad closely for two days and convinced myself that the history given me by the parents was correct. The patient was kept for weeks on the milk which had been his food. He was not allowed even a crust of bread; he had been having bread dipped in meat juice once or twice a day. His temperature was normal. There were one or two large formed movements daily; toward evening the boy would have a profuse movement, partly solid, partly fluid: and of an intensely sour and penetrating odor. The pasteurized milk of the laboratory was stopped and the boy placed upon milk sterilized at 100° C. for forty minutes, with five grains of tannigen, *t.i.d.* The improvement was immediate and progressive. The movements became brown, of normal odor and consistence. The boy gained in strength, and gradually after a week other articles of diet were added to the milk, until a full, properly mixed diet was reached. After a year we find the boy still perfectly well, with the exception of an attack of vomiting and diarrhœa this summer, of a few days' standing. During this time the sterilizer had been broken, the milk was not sterilized, and the boy's illness can fairly be traced to this fact. To-day he is well, and a finely nourished lad.

Epicritical.—Here is a case which is typical of many I have seen, both in private and clinical practice. A subacute diarrhœa of the above character; the physician places the patient on exclusively milk diet, only to aggravate matters. The stools are of an

extremely acid character, even irritating the parts about the anus. No pyrexia but a gradual increasing loss of strength. The milk being pasteurized, immediate improvement on the substitution of sterilized milk. This is only, as I say, one case among many, and it is chosen because the surroundings and milk were all the best that money could procure.

In my clinical work I have made several unsuccessful attempts to substitute milk pasteurized at 75° to 80° C. for the sterilized product. The milk used at my laboratory is delivered by one of the best dairies in town, at a very early hour in the morning. It is then modified according to the Soxhlet formula and sterilized, or the pure milk is sterilized whole for some children.

In pasteurizing the milk, I at first made use of my steam sterilizers, noting the temperature with thermometers, and then, after the milk was kept at 75°–80° C. for forty minutes, it was rapidly cooled and then kept on ice or in ice water until used. When the milk was given away, the people were supplied with orders for ice with which to keep it cold. With the greatest exercise of care, complaints were made that the milk curdled, or that the infants suffered from one of the forms of insidious subacute diarrhœa pictured above. It was then decided this year to use the Freeman pasteurizer, to pasteurize each portion separately, and only one portion at a time, and to keep only one baby under observation at a time.

From those who reported faithfully I learned that the milk which was modified and to which sugar of milk was added kept better than the milk which was pasteurized whole. Some of the parents reported in the summer months that the milk, in spite of its having been kept on ice, turned solid in the bottles. Of course there is with this poor and unlearned class always an element of carelessness, but the fact reported goes to show that milk has a bacterial element which is not affected by pasteurization, which will cause curdling and which will become troublesome at the slightest opportunity.

Clinical Cases.—Case I.—Infant, male, eighteen months old. Had been suffering from simple enteric catarrh. The diarrhœa was first controlled and then the infant was given pasteurized milk, thirty ounces daily. The infant continued to have loose movements at intervals for a month. Once diarrhœa was very serious. The child continued pale and did not increase in weight. Put on sterilized milk.

Case II.—Female infant, four weeks old, partly breast fed. Had now one normal yellow movement daily. Put on pasteurized milk with the breast. The movements immediately became more numerous, five or six daily; sour in odor. After a few days changed to sterilized milk. Baby did well after this.

Case III.—Female infant, seven months old; congenital syphilis. Had been doing well on sterilized milk; put upon pasteurized milk. Had several diarrhœal movements which were not controlled by sterilized milk. All milk stopped; recovery; and baby put on sterilized milk.

Case IV.—Female infant, one year old; had been taking sterilized milk for some time; bowels normal. Put on pasteurized milk. After three days the stools became numerous, six a day, unformed and cheesy; was compelled to go back to the sterilized milk.

Case V.—Female infant, one year old; had been in good general condition; had rachitis. Had been taking pasteurized milk for five days; some days the baby had two or three normal formed movements; other days had diarrhœa. Milk changed.

Case VI.—Infant, five months old; had been taking sterilized milk, and had had five or six movements daily. It was put upon pasteurized milk; the character of the movements, which had been diarrhœal, continued much the same; pasteurized milk discontinued after five days. In this case the pasteurized milk was used because the baby refused the sterilized milk; no better success with pasteurized.

Case VII.—Female infant, six months of age; had taken sterilized milk for a month; had had two normal movements daily, and was in good health. Put upon pasteurized milk. At first it seemed to agree with the infant; then after a few days the mother reported a sharp diarrhœal attack. This was during the coolest July 26th known for years. Pasteurized milk stopped, baby put on sterilized milk; continued well.

Case VIII.—Female infant, nine months old: suffered from a subacute enteric catarrh. Had been under pasteurized-milk treatment for some days without improvement. Diarrhœa alternated with formed movements. Mother complained that milk turned solid over night. Weather warm, milk kept on ice.

Looking over the above cases, we must conclude that there was some irritant substance in the milk. The first case cited is very characteristic. There was in this case no question as to the presence of such disease as typhoid, all this being ruled out. In all these cases bacterial proliferation must be fixed upon as an etiological factor. I mentioned that Russel showed the presence of three varieties of acidifying bacteria in pasteurized milk. Dr. Lewi, working in my laboratory, showed that if milk was pasteurized with the Freeman apparatus and kept at a mean temperature of 28° C. acidity began to develop in five or six hours, and reached its height in twenty-four hours; sometimes in twelve hours at a lower temperature, 23° C. She concluded that when not kept on ice on a warm summer day pasteurized milk has a fairly stationary acidity ten or twelve hours after pasteurization, and twenty hours after pasteurization milk is curdled. The invariable marked acid odor of the stools in many of the above cases points to an acid-forming element as a leading factor in the causation of the diarrhœa.

If milk is sterilized at 90° or 92° C., a temperature first advocated by me and shown later by Flügge to destroy all acid-forming bacteria, we find that without ice the acidity of such milk remains stationary for from three days to three weeks in the warmest weather, and that when it does coagulate it does so with an alkaline reaction due to the peptonization of the milk by the peptonizing bacteria. (Milk sterilized as above shows no change except that of peptonization, even four weeks after sterilization.) In simpler words, the first set of bacteria mentioned in the first part of this paper, the bacterium-lactis class, is rendered inert, and if unprotected with cold the milk suffers only from the peptonizing group.

Flügge showed how the action of even this group may be temporarily rendered inert by cold. But, say the advocates of pasteurized milk, milk pasteurized must be kept on ice. It is argued that in this way the changes noted above are delayed or prevented, but, even granted this is so, the bacteria remain unharmed to cause trouble in the infant stomach and gut.

Both Soxhlet and Plaut (Dr. Lewi) showed that raw milk could be kept on ice unchanged—temperature, 15° C.—for twenty hours; yet no one could think of giving such milk to infants. Flügge says that as far as pasteurized milk is concerned it should be treated for infant use the same as raw milk. What is the extent to which, therefore, our knowledge goes in regard to milk for infant feeding? Milk should be heated at least to a temperature of 90°, 92°, or 100° C., the latter being a preferable temperature, for ten minutes. It should be rapidly cooled and kept cool below 20° C., until ready for use (Flügge). In this way the second set of bacteria, the peptonizing bacteria, is kept inert.

The argument which was first raised against sterilization by Leeds and Davis, that the high heat lessened the digestibility of the milk by coagulating the albumins and changing them, has not been verified after years of work on this very theme.

P. Salomin found that the lactalbumins are separated, beginning at a temperature of 60° C., and completely coagulated at from 72° to 80° C.; so that as far as the lactalbumins are concerned pasteurization has no advantages over sterilization. The gross albuminous precipitates increase up to 100° C. of sterilization, but even here Salomin found that the precipitation of albumins at from 95° to 100° C. amounted only to 0.175 mgm. of albumin for every 100 c.c., a very slight amount, varying with the acidity of the milk and the amount of fat. It has also been stated that the digestibility of the albuminoids in the milk is lessened by the process of sterilization. This has not been borne out by actual study on the waste albumins contained in the faeces of these infants (Bendix and Koplik).

In my own work on the subject it was distinctly shown that, so far as a study of waste products could teach us, there was little difference in the digestibility of raw, pasteurized, or sterilized milk, continuously prepared or modified in the same way, when administered to the same infant. As to the taste of pasteurized milk, this varies, and all observers seem agreed that, as a rule, milk heated at or above 70° C. loses its raw flavor. Pasteurized milk is an uncertain and in some cases a very dangerous food for infants. Sterilization in the household must be carried on in a closed steam sterilizer where the temperature reaches 100° C., or quite close to this point. The temperature should be maintained for a distinct length of time, and after this the milk should be cooled by first placing the bottles in running water, and then on ice or in a refrigerator below 20° C., until given to the infant.

66 East Fifty-Eighth Street.

Therapeutic Indications of Heat.—Dr. Bosanyi (*Pester medicinisch-chirurgische Presse*, October 24, 1897) has commenced a study of this subject. He says that hot baths have been used with success in puerperal eclampsia, and hot douches and applications have been found of value in certain diseases of women. He refers to the treatment of anæmia by diaphoresis and bleeding, which he appears to look upon as a possible substitute for the iron treatment. In the acute infectious diseases, such as diphtheria, influenza, the hot baths or the local application of heat has proved to be of service. Epidemic cerebro-spinal meningitis has been treated with remarkable success by baths at 36° to 46° C. In certain skin diseases, mostly chronic, the hot bath is a valuable remedy. In some circulatory disturbances with dropsy, diaphoretic baths are of value. The use of heat as a therapeutic agent has undoubtedly its limits, and under some circumstances is contraindicated. He thinks that chronic diseases are those most liable to be benefited by this treatment.

Progress of Medical Science.

An Apt Saying.—It had been aptly said that aneurisms of the ascending aorta were those of physical signs, and those of the transverse arch those of symptoms.—Harold Parsons.

Bronchitis and Pneumonia following the administration of ether were often due to the carelessness of attendants in not keeping the patient warm after coming from the warm operating-room to a ward where the temperature was ten or fifteen degrees lower. Sometimes there was pulmonary infection from the inhaler.—H. C. Scadding, before the Toronto Medical Society, November 8, 1897.

An Indication of Fœtal Death is acetone in the urine, reported by Knapp, of Prague. To ascertain the presence of acetone, Jaksch's method is used, which consists of adding to the urine nitroprusside of sodium, and then either caustic soda or potash to alkaline reaction. Acetic acid is then dropped into the fluid until the characteristic purple or violet color develops. Or acetone may be demonstrated by the fuchsin test of Chautard. A solution of fuchsin, 1 to 2,000, is decolorized by sulphuric acid. To make the test, half an ounce of urine is poured into the test tube and a few drops of the fuchsin solution are added. If acetone is present, the color of the urine becomes violet or purple, the depth depending upon the quantity of acetone.

Abscess of the Pelvis.—Dr. F. J. Shepherd exhibited the pelvis of a male before the Montreal Medico-Chirurgical Society, which met on April 23, 1897. One-half of this specimen was dry, the other moist. There were sinuses in the lumbar, sacro-iliac, and gluteal regions, and in the thigh and groin of both sides. The pelvis and sacral regions were filled with pus. On examining the specimen it was well shown how the disease was bilateral and what a small amount of original disease there was. The original disease was altogether confined to the intervertebral substance, between the fourth and fifth lumbar vertebræ, and an abscess cavity was found here which had spread laterally down each psoas muscle, and also down the sacrum into the pelvis. There was no spinal deformity whatever. The dry specimen showed new bone throughout about the lower lumbar vertebræ and the sacrum, but no sacro-iliac disease. The moist preparation well demonstrated psoas, presacral, and lumbar abscesses—all proceeding from the original disease between the fourth and fifth lumbar vertebræ. Dr. Shepherd said this case explained one of the puzzles met with in the surgical wards, when sacro-iliac disease was suspected and abscesses were found on both sides. In the present case the disease could be searched for only in front.

Results of Thyroid Feeding in Insanity.—Dr. Cross (*Edinburgh Medical Journal*, November, 1897) reports the results in twenty patients, suffering from melancholia agitata, melancholia, senile dementia, chronic mania, mental enfeeblement, and dementia, and concludes that all the cases gave a greater or less reaction to the thyroid, viz.: slight rise of temperature, slightly increased respirations, and marked increase of pulse rate, with weakness of heart beat. In all cases the pulse was the first to show any change, and was most affected by the drug. The reaction in all cases became more pronounced toward the end of the treatment, passed off gradually when the drug was discontinued, but was quite noticeable for a week at least. The reaction, too, varied in intensity in different subjects, but not in sufficient degree to admit of

any possible deductions. An interesting feature was that none of the males became excited while taking the drug, although two showed such marked improvement. The author finally makes a plea for a thorough trial of the thyroid in apparently hopeless cases of insanity.

Tuberculin.—Tuberculin is a great help in dermatology, both as a diagnostic and as a therapeutic means. In lupus erythematosus it acts remarkably well as a systemic treatment, but, of course, the locality must be treated with external applications. In a large number of instances I never had any bad effects; and the condemning of tuberculin for fear of spreading tuberculosis is absolutely absurd. The old tuberculin has given more regular reaction, both general and local, than the new tuberculin; and thus far I have found in dermatological work that the old is preferable to the new tuberculin. In cases in which no other remedy has any beneficial influence, and the tuberculin causes the disappearance of the eruption, the healing of the ulcers, and improvement of the general condition, this remedy has to be acknowledged as a great remedy. If relapses occur after ceasing the use of tuberculin, the remedy must not be blamed. It must be used for a long time, in small doses at long intervals, until recovery is assured.—Dr. A. Ravogli, Mississippi Valley Medical Association, October, 1897.

Hæmoptysis Caused by a Wood Louse.—Dr. Paschayan (*La Médecine Moderne*, August 25, 1897) reports a case of a man, thirty years old, who consulted him on July 20th. There had been hæmoptysis with a dry cough. Examination of the lungs, heart, and other organs gave no sign which explained the hæmoptysis. The general condition was perfect, except for a very slight fever. Examination of the throat revealed a small point on the left posterior pillar of the palate from which the blood was flowing. The point was cauterized with perchloride of iron. The next day the patient complained of dryness of the pharynx. There was neither hemorrhage nor fever. A gargle of chlorate of potassium and resorcin was prescribed. The morning of the following day the capillary hemorrhage was repeated, the thermometer showed a higher temperature, and the dryness of the throat was slightly diminished. The gargle was repeated and sixty centigrams of sulphate of quinine was given. The next morning there was a new hemorrhage. With the bleeding the patient noticed a hard foreign body which fell into the spittoon. Examination showed the foreign body to be a wood louse. The bleeding point was again cauterized, the pharyngitis disappeared, and there was no further trouble.

Recent Progress in Ophthalmology.—In the *Boston Medical and Surgical Journal* of January 6th, is published an account by Coppez (taken from *Rev. Gén.*, October, 1896) of a previously healthy young dairymaid contracting tuberculous iritis through bacilli from the udder of a diseased cow having been introduced at the base of the distal phalanx of the ring finger. The course was characterized by inflammatory nodules, limited to the skin and subcutaneous tissue, which broke down and finally healed by an adherent scar. There were sixty or seventy of them in all, which were mostly curetted and cauterized. A careful examination did not reveal any signs of visceral tuberculosis. An iritis with ultimate destruction of the eye appeared early in the disease, and enucleation was done about six months after the first appearance. Nothing abnormal was noticed in the posterior part of the globe, the choroid being scarcely hyperæmic. The iris was the primary seat of the lesion and was invaded in its totality, while only a few and unimportant nodules were noticed in the ciliary processes. Pus from one of the abscesses produced in rabbits a smart iritis and panophthalmitis, and after glandular involvement the animals died in the course of a few months cachectic. In sections the typical bacilli were found occupying their usual relations in the giant cells. The author considers this unmistakable relation between cause and effect to be worthy of record, on account of the great difference of opinion of those who have studied the origin of ocular tuberculosis.

Congenital Absence of Penis.—Dr. Robert T. Harris has, in the *Philadelphia Medical Journal* of January 8th, an article on the congenital absence of the penis, the urethra making its exit into or below the rectum, and emptying the bladder by or exterior to the anus. In this article six authentic cases are cited, illustrating this abnormal condition. Dr. Harris remarks that "as far as can be ascertained there is one male infant born with this abnormity in about thirty million. In the last fifty years England has reported one case; France, one; Germany, one; Austria, one; and the United States of America, two. No comprehensive treatise on teratology or embryology mentions it, nor is it referred to in Ballantyne on 'Diseases and Deformities of the Fœtus.' Jacobson, on the 'Diseases of the Male Organs of Generation,' 1893, pages 482, 609, refers to three of the cases mentioned. Gould and Pyle, on the 'Anomalies and Curiosities of Medicine,' 1897, page 314, report the same three cases. White and Martin, in their 'Genito-Urinary Surgery,' 1897, give one case, while no one seems to have noticed two of the cases to which reference is made."

Surgical Treatment of Acute Rheumatic Arthritis.—In an article by Dr. John O'Conor, in the *Medical Press and Circular*, November 10, 1897, the author relates his personal experience in what may be considered a rather heroic treatment of acute rheumatism, gonorrhœal arthritis, and non-specific rheumatic arthritis. He states that the only successful treatment for a gonorrhœal or a pyæmic joint is immediate opening and irrigation and drainage, and in support of his belief cites five instances in which this method has been followed by recovery, including one of acute epiphysitis with pyæmia. The incision must be large enough to admit the index finger, since lymph coagula are retained in the recesses of the joint which nothing short of digital manipulation suffices to detach. If this plastic material is left behind, the operation would be robbed of its value. For irrigation he employs biniodide of mercury, 1 to 5,000. After drying with gauze, drainage is provided for. The indolent treatment of this affection by blistering and external applications can result only in stiffening of the joint, fibrous ankylosis, either partial or complete, as laid down in most recent text-books. Treves is quoted to the effect that "there is no remedy yet known which can be relied upon." The author suggests the term acute infective arthritis as a substitute for acute rheumatism, which has little etiological or pathological significance. The prefixes gonorrhœal, pyæmic, tuberculous, syphilitic, etc., may be retained, in order to differentiate. The infected joint serves as an incubator in which the poison is elaborated and poured into the circulation. He suggests that recourse be had to surgery, and relates an instance in which success followed the opening of an arthritic joint. In conclusion, he says that when we meet with a collection of staphylococci we rush to operate; but when we encounter a collection of gonococci or rheumatococci we nostrumize, because we entertain some fears of merely opening and draining the non-purulent joint.

MEDICAL RECORD:

THE TRANSMISSION OF SYPHILIS.

THE question of the transmission of syphilis is again provoking much discussion. The point at issue is in regard to the possibility of the disease being transmitted beyond the second generation, and the arguments for and against are many but inconclusive. Transmission to the third generation is interpreted in different ways by various modern writers. Some describe the taint when found in the grandchild as transmission to the second generation; the majority of English-speaking authorities, however, term the disease when twice transmitted transmission to the third generation. This description would appear to be the more correct, as when the disease has been twice transmitted it has existed in three generations.

The opinions held as to syphilis in general and hereditary syphilis in particular diverge to a large and amusing extent. The reports of the numerous researches made and the views of those engaged in elucidating the matter are so conflicting that it is impossible to arrive at a clear conclusion. One well-known English provincial physician has gone so far as gravely to express his belief that the danger attending an attack of syphilis has been altogether exaggerated, and that the disease is no more to be dreaded and no more difficult to cure than an ordinary cold. In regard to the transmission from parent to child, he contends that this is the rarest of all events. On the other hand, there are those who go to the other extreme, and lay to the charge of syphilis almost every known disease. The truth probably lies in the happy medium, and, while it is obviously absurd to designate syphilis as a trifling complaint, yet it is nearly as unwise to endeavor to make it the scapegoat for every disease. That syphilis in civilized countries is not the virulent and destructive disease it was in past days is a notorious fact, but that it can be transmitted is equally as well known. The point in dispute is not in respect to the possibility of its transmission, but as to the number of generations through which the taint may be handed down. Dr. George Ogilvie has recently published a paper reprinted from the *British Journal of Dermatology*, which contains many important facts in relation to this subject. After stating as his opinion that the diagnosis of hereditary syphilis can be made from the patient alone, in infancy as well as in adult life, and after showing that it must be granted once for all that absolutely to exclude acquired syphilis is impossible, he proceeds with these remarks: "On another point, strange as it may sound, it is desirable to come to an agreement, viz., as to what is to be considered hereditary syphilis. That syphilis of the parents, apart from being actually transmitted to the child, may produce in the latter certain pathological states, such as general debility, slow and imperfect development, some backward condition, liability to other diseases, etc., has not escaped the attention of earlier observers. 'Parasyphilis,' as an hereditary condition, is only a new name for an old fact, which, although occasionally doubted or even denied, has on the whole been long recognized. But recently, under the vague term of parasyphilis, all sorts of diseases have been added to the domain of syphilis, the syphilitic origin of which is more than doubtful. Whether in the production of such malformations as clubfoot, harelip, congenital amputation, etc., hereditary syphilis plays any part at all, is a question on which a good deal of difference of opinion seems to exist. Those who express themselves in favor of such a connection do so from an impression formed as a result of their personal experience, rather than from a series of well-authenticated cases sufficiently large to establish a clinical fact. Under no circumstances, therefore, can the diagnosis of hereditary syphilis be based upon symptoms of this kind alone, and even when they appear together with unmistakable signs of heredo-syphilis their connection one with the other must remain doubtful."

Many examples of cases of hereditary syphilis collected from all parts of Europe are then given, which, although as evidence they are by no means unanswerable, still present some arguments in favor of transmission to the third generation.

An interesting feature of the observations of Dr. E. von Düring, of Constantinople, who was last year sent on a special commission into the interior of Asia Minor, is that syphilis was not introduced into these parts until about sixty or seventy years ago, so that the living generation would be the third or fourth since the first appearance of the disease.

Another instructive point brought to light in the present discussion on hereditary syphilis is the growing disbelief in Colles' law. The Frenchmen, Fournier and Diday, affirm emphatically that "if a woman bear a syphilitic infant she must of necessity have had the complaint herself." Mr. Jonathan Hutchinson maintains that exception to Colles' law means reinfection. Dr. George Ogilvie is not in agreement with this view, and considers that it has not been proved. Nevertheless, a belief in Colles' law is still more or less an article of faith with the medical profession in England. Dr. Ogilvie is a disbeliever in the theory advanced by many writers, by whom syphilis is credited with exercising a favorable and far-reaching influence by conferring immunity upon generations of descendants without actual transmission of the disease. In relation to this matter he quotes Professor Neumann, of Vienna, who says: "Having made investigations about syphilis in different countries, I am not

able to say that I have noticed any perceptible difference in the disease in the various civilized countries." Reference is also made to the investigations recently undertaken in India, in the following words: "Our last experience in India is not such as to strengthen confidence in this theory of national immunization. The havoc which syphilis has made there, among a certain class of the population for generations impregnated with the poison, is as bad as or even worse than that caused on virgin soil." From the committee's report it is clear that the malignant and destructive cases were not isolated ones, but were very numerous, and the results so pitiable that "death alone can solve the difficulty."

The case for the transmission of syphilis to the third generation must be regarded as on the whole not proven; the clinical facts adduced in support of the theory do not rest upon a sufficiently solid basis, and have for the most part but an anecdotal value. While it cannot be denied that the "dystrophic" influence of syphilis may make itself felt in the third generation, yet until more convincing proof is brought forward to this effect the majority of medical men will remain sceptical. This state of affairs must continue so long as the general practitioner exhibits his present condition of indifference on the subject.

QUARANTINE POLITICS AT MOBILE.

It seems that the gentlemen who were invited to Mobile from the south Atlantic and Gulf States to discuss matters relating to topics kindred to yellow-fever epidemics and internal and maritime sanitation were served with a dish of States'-rights politics for about two-thirds of the time, and that the elaborate programme, covering thirty-seven papers on various subjects, did not cut any figure in the business of the convention. Those who were allowed by the executive committee to read papers proved to be gentlemen whose views on States' rights and domination of the federal government, etc., were bitterly expressed, and the whole tone of their papers was an attack on national quarantine and in favor of local control. It has been charged in some of the papers in the South —notably the *Atlanta Constitution*—that it would be a convention engineered by a self-constituted executive committee, which was endeavoring to secure only such delegates as were opposed to a national system of quarantine. We commend to the students of political management the system devised by the leading spirits of this convention. An executive committee, elected by i self, installed a permanent chairman of the convention without asking the members to approve its choice; this chairman named the committee on resolutions, among whose members appeared delegates f.om five Northern States not originally having membership in the convention—and of these, two, strangely enough, had been prominent advocates of a certain public-health bill. What such a committee would do ne d not be detailed. That it did not do all the managers hoped was due to the good sense of a minority, who found they had gotten into a quarantine caucus under the impression that it was a sanitary convention. The following resolutions were passed:

"*Resolved:* 1. That it is the sense of this convention that Congress be requested to provide for a department of public health as soon as practicable.

"2. That it is the sense of this convention that Congress should enact laws to provide for an efficient maritime quarantine, to be uniform and impartial in its application to the different commercial ports of this country, so as to give no one or more of them undue commercial advantage over the others, and to be enforced by the several State and municipal quarantine or health boards, if they will undertake to do so, leaving also to the States the power to prescribe and enforce additional reasonable safeguards of the health of the communities, provided that such State action shall not unreasonably obstruct commerce.

"3. That Congress should aid the several States in establishing and maintaining uniform, reasonable, and efficient quarantine laws for affecting but not regulating interstate commerce, leaving to each State adequate power to protect, as it shall deem best, the lives and health of its people.

"4. That Congress should leave exclusively to the States the regulation of their purely internal commerce and the provision of such quarantine or sanitary laws as they may deem advisable to that end.

"5. That in the framing of quarantine laws and regulations, and in their enforcement, Congress should avail itself of the learning, experience, and ability of the medical profession in the fullest measure possible, and especially by way of an advisory council."

As near as we can make out, this leaves the question about where it was before the convention met. We had hoped to be able to record some beneficial results to the great questions of public health which we were interested to know were to be under discussion by gentlemen thoroughly competent to throw light upon them. We hope they will be given a chance for inspection in the printed proceedings of the convention, if the managers intend to make a published report. That much certainly is due the public, which encouraged its deliberations and whose sympathies were engaged in its behalf.

What Hospital Patients Cost in England.—An English weekly journal says: "The average cost of patients at the various London hospitals differs enormously. Taking the amount at so much a day, according to the number of in-patients treated, the figure ranges from about $2.50 at the Chelsea Hospital for Women to less than 50 cents at the Western Ophthalmic, and 50 cents at the National Orthopædic and the Central London Ophthalmic. Among the expensive institutions are the British Lying-in Hospital, $2; Royal Hospital for Diseases of the Chest, $2; Metropolitan, $1.80; Royal Eye, $1.75; Cancer and Samaritan, free for women and children, $1.70. On the other hand, among the cheapest hospitals are the West London, 55 cents; East London, children, 65 cents; Italian, 70 cents; and the Great Northern Central, 72 cents.

News of the Week.

Catheterization of the Male Ureters.—Some two weeks ago Dr. Howard Kelly, of Baltimore, gave an interesting demonstration of his method of catheterizing the male ureters, in Dr. Abbe's clinic at St. Luke's Hospital in this city. The patient was a man with supposed renal calculus. He was etherized and the straight endoscope was inserted into the bladder while he was in the dorsal decubitus. Then he was raised to the knee-chest position, and it was found to be thoroughly practicable to inspect all parts of the bladder illuminated by light thrown from an electric head illuminator. The ureteral orifice was readily demonstrated to several of those present, and then the long flexible catheter with its stylet was instantly passed in and onward nearly to the kidney. The endoscope being withdrawn and the patient returned to bed, the urine began to flow in a few minutes, and after two test tubes full were obtained the catheter was withdrawn. Had it not been for the time occupied in demonstration, the entire procedure would not have consumed more than four or five minutes. The value of the knee-chest position is that what urine remains in the bladder falls down toward the internal meatus and leaves an unobstructed field for study. Dr. Kelly demonstrated also that when the prostate is enlarged and that portion of the canal is tortuous, the straight endoscope can hardly be passed beyond the prostate, so that this method of ureteral catheterization is not feasible in all subjects. The operator said that this was the last demonstration he expected to make of this method, since it was outside his especial field, and he left it therefore to be developed by the general or genito-urinary surgeon.

Cure of Tuberculosis.—Among the few scientific essays handed in in competition for the Audiffred prize this year, at the French Academy, was one from Hirschfelder, of San Francisco, on his oxytuberculin, and another from two Mexican physicians on the effects of rarefied air. Neither was considered worthy because of insufficient animal experiments, and the prize was not awarded.

Hotel Accommodations at Denver.—The hotel proprietors in Denver, with the usual shortsightedness of people of that class, are purposing to make it as uncomfortable as possible for those in attendance at the meeting of the American Medical Association in June, in order that the meeting may be made as profitable as possible to themselves. The manager of one of the leading hotels in that city has already refused to make any reservations unless two persons will consent to occupy a single room. How many he expects to put into a double room we have not yet ascertained.

A Safety Club.—Dr. A. W. Nelson, of New London, Conn., has invented a policeman's club, coated with semivulcanized rubber, which, he claims, is sufficiently yielding to prevent a blow with the club from fracturing the skull, while still being sufficiently convincing to the unruly arrestee.

A Threatened Calamity.—Our agitated contemporary, *The Post-Graduate*, remarks, anent the dispensary bill before the State legislature: "We shall not give up the regulation of our affairs to a State board of charities, unless the legislature and the courts say we must do so. If they do, we shall seriously consider the subject of placing the Post-Graduate Medical School and Hospital in a city a little more jealous for its medical supremacy than is New York."

Obituary Notes.—Dr. Thomas H. Atkinson, one of the city physicians in Jersey City, died on February 4th, of typhoid fever. He was a graduate of the College of Physicians and Surgeons in this city. He was twenty-five years of age.—Dr. Arnold Stub died last week at his home in Brooklyn. He was born in Elbing, Prussia, in 1832, and came to America when twenty-four years old. He served throughout the civil war, having been appointed assistant surgeon of the nineteenth regiment, New York State volunteers, in 1862. He was afterward promoted to the rank of surgeon, and later was appointed by General Hancock medical purveyor of the middle military division. He returned to Brooklyn and resumed his practice at the end of the war. He leaves a widow and three daughters.—Dr. George C. Briggs, of Burlington, Vt., died February 11th, aged sixty-eight years. He was formerly professor of materia medica in the University of Vermont. In 1872 he represented the town of Franklin in the State legislature. He was a graduate of the University of Michigan in 1853.—Dr. Oscar A. Menocal died on February 9th, in Brooklyn, of tuberculosis. He was twenty-eight years old. He was graduated from Columbian University, at Washington, D. C., and practised medicine for five years in that city. His final illness dated from last August.—Dr. J. S. Isham, of Cleveland, Ohio, died in that city on February 10th, at the age of fifty years. He was a graduate of the Bellevue Hospital Medical College in the class of 1874. He leaves a widow and one son.—Dr. John Cronyn died on February 11th at his home in Buffalo. Dr. Cronyn was born, December 22, 1825, in Black Rock, a suburb of Cork, Ireland. He came to this country in 1837, and in 1852 obtained his degree of M.D. from the University of Toronto. He moved to Buffalo in 1859. He was an ex-president of the New York State Medical Society.—Dr. Robert A. Wheaton, of St. Paul, died suddenly in that city on February 13th, at the age of thirty-five years. He was born at Northfield, Mass., and was graduated from Harvard Medical School. He was professor of minor surgery at the University of Minnesota.—Dr. Lewis R. Hurlbutt died at his home in Stamford, Conn., on February 14th, of pneumonia. He was seventy-eight years old.—Dr. Bickham, of New Orleans, died there on February 14th, aged sixty-nine. He was a native of Covington, La. He began the practice of medicine in Texas, but later went to New Orleans, where he became successively house surgeon of the Charity Hospital, demonstrator in anatomy of the Medical College, vice-president of the Charity Hospital, a member of the board of health, of the board of administrators of Tulane University, and also a member of the legislature. He was one of the board of yellow-fever experts in the late epidemic.

The Hospital Saturday and Sunday Association.—In consequence of a sleet storm, the attendance at church on Hospital Sunday was very small, with the natural result of a relatively small collection for the hospitals, the falling off in many instances being more than one-half as compared with former years. But for the untoward weather, the executive committee believes the church collections would have been the largest in the history of the association, since in a few instances when the collection was deferred to the following Sunday there was an increase in the offering over that of any previous year. The committee has therefore issued a special appeal to the public for additional contribution , offering "as a return for the favor . . . that an application for free hospital service in behalf of an employee or other sick person, made to the general agent of the association, will receive prompt attention."

The Late Dr. Thomas Hanlon Atkinson.—At a special meeting of the Practitioners' Club of Jersey City, held February 6, 1898, a committee was appointed to take action upon the death of our deceased brother, Dr. Thomas Hanlon Atkinson, and will offer the following report at the next regular meeting of the society:

"While as mortal men we can but rest content to live this life on earth as best we may, waiting for the summons to bow in obedience to the command of His eternal will, we still cherish the hope and are led to think that youth may always live the life of threescore years and ten: but when the earlier call is sounded and the time has come for us to end this strife on earth, we must cheerfully obey and willingly onward march to that eternal life 'which has been prepared for those that love Him.'

"Dr. Thomas Hanlon Atkinson has been taken from us in the prime of his life, when all was bright before him and the ardor of youth was stamped upon his brow.

"We had learned to love and respect our departed brother, and our associations with him were always pleasant and full of interest.

"We mourn the loss which we have sustained, and cruel is the blow which has taken from us for the first time a member of our society.

"While others may hope to take his place, still will we hold in reverence the one who has gone before us, resting content with the knowledge that he has claimed eternal life and reached the goal for which we can but strive to take.

"*Be it Resolved*, That we spread in full this tribute of respect upon our minutes, and a copy be forwarded to the Jersey City press, the medical press, and to the family of the deceased."

[Signed] G. K. Dickinson, M.D., J. M. Rector, M.D., F. F. Bowyer, M.D., *Committee.*

At a special meeting of the committee on necrology, of the District Medical Society, County of Hudson, State of New Jersey, held February 6, 1898, the following resolutions were unanimously adopted, and will be reported at the next regular meeting of the society:

"*Whereas*, Death has removed from our midst our beloved colleague, Dr. Thomas Hanlon Atkinson, a man who has merited the respect of his associates and the confidence of a large circle of friends and patrons in Jersey City; be it therefore

"*Resolved*, That in the loss of our late member, Dr. Thomas Hanlon Atkinson, the society mourns one of its most genial fellows, and the medical fraternity loses one whose future gave great promise;

"*Resolved*, That we hereby extend to the family of our lamented brother our heartfelt sympathy;

"*Resolved*, That these resolutions be spread in full upon our minutes, that they be published in the *Jersey City Evening Journal*, the Medical Record, the *New York Medical Journal*, the *Medical News*, and that a copy be sent to the family of Dr. Thomas Hanlon Atkinson."

[Signed] J. M. Rector, M.D., President; Henry Spence, M.D., Secretary; H. H. Brinkerhoff, M.D., Treasurer; J. A. Exton, M.D., Reporter, *Committee.*

Dr. John Gilbert Truax died February 16th, at his home at 117 East 127th street. He was born at Durhamville, Oneida County, N. Y., in 1848. After being educated at the University of Michigan he was graduated from the Rush Medical College in Chicago in 1871. From the time of his graduation until 1876 he was physician at the Kloman mine at Marquette, Mich. After coming to this city he became associated with the Harlem Hospital.

The Central Park Ambulance Service was abolished on February 1st, but so much inconvenience and delay has resulted from this that President Clausen, of the park board, has requested President York, of the police board, to have it restored.

Influenza in London.—The death rate in London rose last week to 21.5, the increase being due chiefly, it is thought, to the prevalence of influenza.

Respiratory Heart Movements.—A special cable dispatch to *The Sun* from Paris announces gravely that Professor Bouchard has discovered a new movement of the heart by means of the Roentgen rays. It is a rhythmic dilatation during respiration and is not connected with the ordinary movements of the heart.

Disease in Berlin.—An epidemic of some disease resembling in its chief symptoms trichinosis, but which is pronounced not to be trichinosis, is prevailing in Berlin.

Asking Much of Congress.—A resolution adopted by the quarantine convention in Mobile on February 11th declares that "it is the sense of this convention that Congress be requested to provide for a department of public health as soon as practicable; that Congress should enact laws to provide for an efficient maritime quarantine, to be uniform and impartial in its application to the different commercial ports of this country; that Congress should aid the several States in establishing and maintaining quarantine laws; that Congress should leave exclusively to the States the regulation of their purely internal commerce and the provision of such quarantine and sanitary laws and regulations as they may deem advisable to that end."

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Thirty-Sixth Regular Meeting, Held on Friday, January 7, 1898.

DR. W. GILMAN THOMPSON, PRESIDENT, IN THE CHAIR.

A Case of Spurious Appendicitis.—The patient, presented by DR. JOSEPH D. BRYANT, was a man, aged forty-seven years, who was admitted to Bellevue Hospital on December 17, 1897. He was an architect by profession, and at times indulged in alcoholic stimulants to an inordinate degree. At the time of his admission to the hospital he was supposed to be suffering from appendicitis. An examination showed that his pulse and temperature were normal, but he complained of extreme sensitiveness in the right iliac region. There were two scars in this region, and on close questioning the patient admitted that in July, 1895, he was operated on for appendicitis and the appendix removed. Nine months later he again developed symptoms of appendicitis, and another surgeon opened the abdominal cavity and removed, as the patient was informed, "a piece of diseased tissue." Dr. Bryant said that this patient illustrated the uncertainties of appendicitis. When the man recently presented himself at the hospital, he was just recovering from an alcoholic debauch, and his only symptom of appendicitis was the extreme hyperæsthesia of the abdomen in the right iliac region. The speaker said it occurred to him that the alcohol might have stimulated the symptoms which induced the surgeons to operate in the two previous instances.

DR. GEORGE L. PEABODY said that in these days of frequent operations for appendicitis the probability was that a frank confession on the part of some operators would lead to the discovery of quite a number of cases similar to the one described by Dr. Bryant. The speaker said he at present had under his care a woman with typhoid fever, who early in the course of her disease was operated on by a well-known surgeon, under the impression that she had appendicitis. The case proved to be one of typhoid fever, from which she was now convalescing. Her treatment, however, was much interfered with by her abdominal wound, which was of course unhealed when antipyretic treatment became necessary. She could not be bathed in a tub in the usual way; baths were administered in bed instead, with the usual frequency but with much less obvious benefit.

DR. A. A. SMITH said he also knew of an instance in which a typhoid-fever patient was operated on, under the impression that the case was one of appendicitis. This patient also recovered, but in spite of this fact, the speaker said, he thought Dr. Peabody would agree with him that an operation for supposed appendicitis was not a necessary or even a desirable adjunct in the treatment of typhoid fever.

DR. BEVERLEY ROBINSON said he knew of an instance in which about a year after removal of the appendix there was a recurrence of symptoms similar to those of the original attack. The patient was not operated on again and no abscess was made out, but the speaker thought it possible that in such a case the symptoms might be due to a localized peritonitis occurring after the removal of the appendix.

Operation for the Relief of Prolapse of the Rectum.—DR. JOSEPH D. BRYANT presented a man who had first come under his observation in 1893. The patient at that time was suffering from a marked prolapse of the rectum, for the relief of which he had been unsuccessfully operated on a number of times. At the time of the man's admission his condition was such that a radical operation was not warranted. About six months later an artificial anus was made in the region of the sigmoid flexure, with the view of side-tracking a certain amount of the fæcal discharge, and later, if necessary, excising the rectum. After this the man got along so well that for over two years he was not anxious to have anything more done. The infliction increasing, he was operated on again, October, 1896. The abdominal cavity was opened anteriorly, and the prolapsed gut drawn upward and sutured to the peritoneum and abdominal wall. The man made a good recovery, and since then there had been no recurrence. A very small opening still persisted at the site of the artificial anus made in 1893; this did not cause the patient any trouble excepting when he suffered from diarrhœa.

DR. WILLIAM T. BULL said he was very much interested in listening to the report of Dr. Bryant's operation for the relief of prolapse of the rectum, but he did not quite understand whether Dr. Bryant regarded it as a success or not. By the method described one might succeed in pulling up all the coats excepting the mucous membrane, and he gathered from Dr. Bryant's description of his case that there was still a prolapse of the mucous membrane. The only operation in these cases with which he had had any experience was the method of excision of the prolapsed portion or amputation of the rectum. This he had done in two cases, with results which were entirely satisfactory during the period the patients were under his observation—about one year after each operation. There was no relapse.

DR. BRYANT said that Dr. Bull was correct in his statement that, while the muscular coat of the bowel was drawn up very readily, there still remained some relaxation of the mucous coat. To this the speaker said he had intended to apply longitudinal cauterization, to remove it with clamp and cautery. This operation for prolapse of the rectum, Dr. Bryant said, was not a new one. It had been performed by various operators in twenty-nine cases, but, in view of the fact that it was first done in 1889, it could not now be said what the final outcome of this operative procedure would be. Of the twenty-nine cases on record there had been no return of the prolapse in twenty-two; in three there had been a partial return, and in four no benefit was secured by the operation. No death had occurred from the operation, and the patients had recovered promptly.

Suggestions as to Prophylaxis, Contagion, and Treatment of Pneumonia.—DR. BEVERLEY ROBINSON contributed this paper (see page 253).

DR. WALTER B. JAMES said he had never seen a case of acute lobar pneumonia which justified the assumption that it was the result of infection from another case.

DR. G. L. PEABODY said he could not agree with the statement made by the reader of the paper that it was possible to produce an aseptic atmosphere in the sick-room by the vaporization of creosote. Whether inhalations of creosote or any other agent in the form of vapor could materially affect the mucous surface of the respiratory tract was quite another question, but the speaker thought that any vapor which would prove fatal to the germs of pneumonia would at the same time be dangerous to human life. It was now a well-known fact that pneumonia might be, and often was, the result of a variety of micro-organisms—a mixed infection—and for that reason it was far beyond our power to combat the disease with any specific antitoxin, such as was employed in diphtheria. The speaker said that in his hands the antitoxin treatment

of pneumonia had not produced very brilliant success. About two years ago he bled a patient who had defervesced from lobar pneumonia, but still showed the physical signs of the disease. About twenty ounces of blood was taken, and its serum injected in divided doses into three patients suffering from pneumonia, the treatment covering a period of a week or ten days. In one of the cases the crisis appeared to be hastened and the patient made a good recovery; the second case was not at all influenced by the treatment and the patient died after a rather severe attack of pneumonia; the third patient ultimately recovered after an average duration of symptoms. Dr. Peabody said that last April he had treated eight cases of lobar pneumonia with subcutaneous injections of antistreptococcus serum, and in those cases the results were usually good. At the same time the epidemic was a mild one, and he did not ascribe the results to this method of treatment. The speaker said he had come to the conclusion that an intelligent symptomatic treatment was the best one to employ in pneumonia, according to our present possibilities. The pain should be relieved by morphine or hot applications; the cough, if it was distressing, by inhalations of chloroform or one of the various cough mixtures, and, if the symptoms demanded it, we had in the cold bath a remedy which was distinctly valuable. In all cases, especially those of the alcoholic variety, in which the patients were delirious and had a high temperature, no matter how great the prostration, the cold bath with friction as in typhoid fever, and repeated as often as necessary, up to once in three hours as a maximum of frequency, was the most important addition to our therapeusis in recent years. It was usually followed by a restful sleep, which often lasted for several hours. Dr. Peabody said he had never seen pneumonia spread from patient to patient, or to the nurse, or to any other member of the family. He did not wish to say that such infection did not occur, however, and its possibility should not be overlooked, although the necessity for isolation was not to be compared with that required when we had to deal with a case of scarlet fever or any of the other well-known infectious diseases. In conclusion, Dr. Peabody said he thought alcohol was the best heart stimulant in pneumonia. His results with digitalis and strophanthus in this disease had not been very good.

Dr. Andrew H. Smith said he had seen only one case of pneumonia in which he had reason to believe that the disease was the result of direct infection; that was the case of a hospital nurse, who, while attending very assiduously to a pneumonia patient, contracted the disease and died. The speaker said that, according to the recent observations of certain authorities, the original theory that in order to communicate either tuberculosis or pneumonia the sputa must be in a dry condition was questioned; since it was asserted that a person suffering from one of these diseases might by coughing exhale into the atmosphere a spray which would contain the micro-organisms of the disease, and that these might float in the air for several hours and exist as a distinct source of danger to the well. Dr. Smith said he agreed with Dr. Peabody that at present the symptomatic treatment of pneumonia was the most satisfactory one. He believed, however, that the time would come when pneumonia would be treated to a considerable extent by inhalations, especially if they could be resorted to early, before the alveoli were completely occluded. It was a well-known fact that there was no necessary relation between the amount of lung involvement and the danger in which the patient was placed; the latter depended chiefly upon the virulence of the systemic infection; yet there was a certain proportion of cases in which the lung conditions played a very important part, and death occurred as the result of overstraining and exhausting the right heart. The latter were usually alcoholic cases in which the vascular system was impaired. Dr. Smith said that one writer had reported excellent results from the persistent use of chloroform inhalations. If these reports were to be credited, it was probable that the beneficial effects of the treatment were due not simply to the soothing effects of the drug on the nervous system, but to its germicidal action as well. This action might not be sufficiently pronounced to destroy the life of the germ, but might be sufficiently so to inhibit its growth. According to Sternberg, so weak a dilution of turpentine as 1 to 75,000 would inhibit the growth of certain germs, such as Friedländer's pneumococcus. Pneumonia was essentially a process of germ culture. We had in the lungs the exceptional condition of air spaces which were in very close relation with an unlimited quantity of blood supplied through the functional circulation, and at the same time the structure of the lung was maintained by an entirely different circulation—that is, from the bronchial vessels. In a typical case of croupous pneumonia we had an infinite number of culture tubes or tiny test tubes which contained a culture medium supplied by the functional circulation and in which a rapid production of germs went on; this process did not necessarily involve to any great extent the actual structure of the lung. A proof of this was the rapidity with which the process in the lung subsided, leaving the lung structure just as it was before. There was no destruction of lung tissue as in gangrene, in which the process probably actually involved the nutritive circulation. In closing, Dr. Smith expressed his belief that if turpentine or creosote could be introduced into the lung in considerable quantities in a case of pneumonia, it would at least lessen the activity of the process by which these germs were multipled and by which the formation of the toxins was carried forward.

Dr. F. P. Kinnicutt said that in the majority of cases of pneumonia many of the symptoms, and certainly the fatal issue, were attributable to the general toxæmia rather than to mechanical interference with respiration or circulation. This was strikingly shown in the rapid fall of temperature and pulse in defervescence, the physical conditions in the lung remaining unchanged. As regarded treatment, Dr. Kinnicutt said that the results of the symptomatic treatment of pneumonia certainly had not been encouraging. It had not succeeded in reducing the mortality to less than thirty per cent. in the great hospitals. In view of such figures, it must seem that all means directed to other than a simply symptomatic treatment should be carefully considered. A specific treatment with antitoxins was perhaps not a therapeusis of the future. That different varieties of pathogenic micro-organisms were capable of producing a true lobar pneumonia was believed by many at the present time. In streptococcus pneumonia the antistreptococcus serum might be used, and indeed its use apparently had been attended with benefit. In cases in which the toxic symptoms were marked, with high temperature, delirium, etc., the cold-water treatment in many instances in his personal experience had proved very efficient. He believed that its good effect was something more than the reduction of temperature attainable by its employment, that it probably acted as a potent stimulus to the nervous system. Inhalations of creosote, he thought, might be of value in ameliorating some of the symptoms of the disease.

Dr. A. A. Smith said he thought the question of the communicability of pneumonia was still unproven. He recalled several instances in which the disease was apparently communicated from one to another; one instance in which four members of the same family developed the disease, one after another. The speaker

said he accounted for this by the fact that the members of that family were greatly interested in each other, and the worry and anxiety attending the care and nursing, the inability to take food, and the want of rest had diminished the resisting-power in each case. In another instance a mother, nursing a child suffering from pneumonia, had developed the disease. The worry and anxiety had in the same way lessened the resisting-power. All practitioners had seen in the large hospitals pneumonia patients occupying beds directly next to patients confined by illnesses of one kind and another, and yet how rare it was to see cases of pneumonia develop in hospitals, as the result of such apparent exposure. The strongest argument in favor of its communicability was to be found in the reports of large numbers of cases occurring, one after another, in institutions where many persons are confined in close quarters, as in prisons and other like places.

Dr. Smith said he was optimistic enough to believe and hope that we might some day treat pneumonia by means of an antitoxin with satisfactory results. He was in accord with what had been said regarding the value of the cold bathing in serious cases of pneumonia. He did not favor the plunge bath, but rather the modified bath, sponging, "bed bath," local applications of cold. Within the past two or three years he had used with very satisfactory results cold compresses applied to a portion of the body, preferably to the thorax, as being more convenient. He used this kind of pack at a temperature of 70° or 65° F., depending on the severity of the case and the effects produced, changing the pack every hour during the day and every two or three hours during the night. He did not believe it produced any effect on the local process, but it gave great comfort, quieting the nervous manifestations, producing sleep, improving the pulse, and lowering temperature. It seemed to him that any treatment which made the patient more comfortable must influence favorably the progress of the disease.

Dr. Robinson, in closing the discussion, said he did not agree with those who spoke in favor of the cold baths in pneumonia. He did not think they were indicated in this disease, and even in typhoid fever he thought the value of this therapeutic measure had been overestimated. In pneumonia, particularly in the early stage, as well as in other forms of bronchial inflammation, inhalations of creosote proved very beneficial. The speaker said he had given this remedy repeated trials in pneumonia and felt convinced of its utility. As regarded the treatment of a failing heart in pneumonia, Dr. Robinson said that in some instances not much could be done for it. He had often employed alcohol, strychnine, and digitalis in such cases, without much apparent benefit.

THE NEW YORK MEDICO-SURGICAL SOCIETY.

Stated Meeting, February 7, 1898.

John Blake White, M.D., President.

The General Diagnosis and Treatment of Acute Intestinal Obstruction.—Dr. Frederick Kammerer read a paper with this title. He said that it was well to differentiate between cases which are acute anatomically and clinically and those in which an acute attack was engrafted upon a chronic condition. Habitual constipation alternating with diarrhœa might have been, for a long time, the only indication of a gradual narrowing of the bowel. Suddenly complete obstruction became established. Such cases often presented the same clinical appearance as those of acute obstruction. He had met with five cases of this kind, in all of which the large intestine had been the seat of disease. In four of them constricting cancer was the cause, and in one the trouble arose from adhesions to the gall bladder. In only one had he been able to make the diagnosis before operation, but in all there were signs pointing to obstruction rather than to strangulation. A high degree of stenosis might exist for a long time without giving rise to well-defined symptoms of obstruction. This was more especially true of the small intestine, because of the greater fluidity of the contents of this portion of the bowel. The explanation of this absence of symptoms seemed to be in the compensatory hypertrophy of the muscular coat above the seat of stenosis. It was only when this hypertrophy became insufficient, or the stenosed opening became blocked with food, that the patient was made aware of the existence of the obstruction by the development of colic.

Important Diagnostic Signs. — The speaker laid great emphasis upon the presence of visible intestinal peristalsis as a diagnostic sign of great importance, and reported several cases illustrating its value. Some authors, he said, believed that this sign was rarely met with, but, according to his experience, it was present at some moment in all acute cases, and could be detected if sufficient attention was given to its discovery. Another important sign was localized meteorism. The gases formed in the occluded bowel were not absorbed and removed, and hence the loop became distended before the other loops of intestine more distant from the seat of the stenosis. This sign was especially valuable, because it often enabled the surgeon to locate the obstruction. Localization of pain in the small intestine, as had been well shown by Treves, could not be considered of much importance, though undoubtedly the pain was more intense when the small intestine was involved than when the large bowel was the seat of stenosis. In every case of acute intestinal obstruction that he had met with, the condition of collapse had been well marked, and had been more pronounced in obstruction of the small than in obstruction of the large intestine. In volvulus of the sigmoid flexure the collapse was usually of the severest type, and the rapidity with which it often set in seemed to confirm the view that it was largely due to nerve reflex.

As to the treatment, laparotomy was generally indicated. The location of the incision was of much importance. When the seat of obstruction could be determined with considerable accuracy, the incision should be made in the median line, or at the outer border of either rectus, depending upon which approached most nearly to the supposed seat of the trouble. The operator should be very cautious about exerting even gentle traction on the coils of intestine. For this reason he did not agree with those who always favored making the median incision. Of course, if there was doubt regarding the situation of the lesion, an incision should be made in the median line, from the symphysis to the umbilicus. His rule was to pass his hand first into the cæcal region, and then toward the sigmoid flexure in a gentle search for the point of occlusion. Intra-abdominal search could be accomplished, however, only at the cost of much handling of the intestine and loss of time. He had not derived much benefit from puncture of the bowel and evacuation of gas, because it was a tedious process, and difficulty was often experienced in replacing the bowel. An artificial anus in the small intestine should be rarely established—only when the condition of the patient was such as to render any other procedure hopeless. It was true that certain forms of obstruction, such as intussusception and acute closure of a chronic stenosis, might be relieved without surgical

interference, and that in very exceptional cases volvulus might be recovered from spontaneously. The best medical treatment seemed to be the administration of opium and lavage of the stomach. In particularly acute cases, if the lesion could be localized within the first day or two, an attempt might be made to relieve the obstruction by the measures just mentioned; if, however, there was much doubt, no time should be lost in resorting to operation. Dr. Kammerer thought that the best results would be obtained if all cases of intestinal obstruction were operated upon as soon as the diagnosis had been made, although he would admit that this would be very unscientific.

Inflammatory and Non-Inflammatory Obstruction.—Dr. Lewis A. Stimson said that he had been very much interested in the remarks made about visible intestinal peristalsis, because he had not noted it in the cases that had come under his observation. This might be because he had not looked for it specially, but he could hardly believe it would be observed in very obese subjects. Then again, however constant it might be in chronic obstruction of the intestine, it did not seem to him to furnish a proper guide to the nature of the obstruction. It was necessary, in other words, to know something more than the mere fact that obstruction existed. Mechanical obstructions might be either inflammatory or non-inflammatory. It was of the utmost importance, for both the physician and the surgeon, that the cases should be properly separated into broad classes. We should divide them into mechanical and functional. In cases of mechanical obstruction—*i.e.*, those in which the lumen was occluded by some growth or by some pressure from without—we must determine whether that obstruction was due to a cause which also produced an inflammatory condition, or not. Inflammation might be present, and this depended very largely upon the time at which the case was first seen—in other words, the inflammation might be incidental or essential. For example, a simple band running along a loop of intestine might cause obstruction, but no inflammation, mechanical violence, or peritonitis, and this condition might continue for a week without the slightest sign of peritonitis. If it was high up in the intestine there might not even be any abdominal distention. On the other hand, if a knuckle of gut was caught so that its mesentery was pinched, then there would be all of the symptoms of a strangulated hernia. In the first case palliative measures were appropriate; the second demanded prompt operative interference. But it was difficult to distinguish between these cases, because the surgeon did not usually see the patient until laxatives and enemata had been given or lavage of the stomach had been practised. The abdomen had already become greatly distended, so that the examination had no practical value, and the surgeon's only reliance was upon the history. The age of the patient gave a clew to the nature of the strangulation, for, if the patient was over fifty years of age, in nine cases out of ten the obstruction would be found to be due to a malignant growth of the large intestine. To be sure, there might be a volvulus, but this was a very rare condition—he had seen only two cases of volvulus in twenty years. In cases of cancer of the intestine he had found one symptom very constant—*i.e.*, a slight, dull pain at some one point in the intestine for weeks or months before the acute symptoms developed. It was very rare to find these neoplasms in young people. Two cases were cited in which the presence of supposedly malignant neoplasms had been proved by inspection, yet the patients regained perfect health and the tumors spontaneously disappeared. He was inclined to think these growths in young people were syphilitic.

Collapse.—That collapse was not dependent upon the mere obstruction of the intestine was shown by the fact that stenosis of the bowel might exist for a long time without collapse, but if in addition there was strangulation collapse almost immediately developed. In non-inflammatory obstruction the urgent indications might be met by establishing an outlet for the fæces.

A Ghastly Record.—The record of laparotomy for intestinal obstruction was a ghastly one. In cases of strangulation death was certain, and the surgeon must decide whether or not he was willing to hasten the fatal termination by operating. Some years ago Nélaton had laid down the rule that in the majority of cases it was safer and better to make an incision in the right iliac region and incise the presenting intestine. This procedure would very commonly meet the urgent indications, and not subject the patient to great risk. It could be done quickly, and even without a general anæsthetic.

Peristalsis may be Visible in Obese Individuals.—Dr. A. G. Gerster said that he had not infrequently observed the characteristic peristaltic motion of the intestine which was acutely occluded, and especially in cases of chronic obstruction in which there was a gradual narrowing of the lumen, as from cancer. He had observed this even in very obese individuals. If the peristalsis could not be seen, still it could often be felt. Early opening of the intestine on the proximal side in these cases usually gave very good results. They were not very urgent, and the surgeon would often have four or five days in which to decide regarding the treatment. Dr. Gerster described a desperate case of carcinomatous obstruction of the bowel, in which the distention of the bowel had been so extreme that it had not been feasible to stitch the bowel to the abdominal wall, as in the ordinary operation for colotomy. He had, therefore, surrounded the presenting portion of intestine with iodoform gauze, and had freely incised it. This protection of the general peritoneal cavity had proved entirely sufficient, and the patient had made a good recovery from the operation. It was very important to observe the distinction made by Dr. Stimson between non-inflammatory and inflammatory obstruction. In the former case the symptoms were rarely very acute; in the latter, when the circulation in the wall of the bowel was interfered with, there would be early, frequent, and severe vomiting.

Nélaton's Procedure Recommended.—In those cases in which palpation and the history did not furnish sufficient data for a diagnosis, he also favored Nélaton's plan of making an incision in the right iliac region, and incising the bowel which there presented. If the surgeon was associated early with a physician in the treatment of cases of intestinal obstruction, comparatively few would be allowed to reach the hopeless stage before an operation would be undertaken.

Obstacles in the Way of the Surgeon.—Dr. Parker Syms said that the chief difficulty the surgeon had to contend with in these cases was the lack of personal knowledge of the conditions present in the early part of the onset. The history was often very misleading—as, for example, in the chronic cases, in which it usually dated only from the onset of the acute symptoms. In cases of inflammatory obstruction it seemed to him that Nélaton's plan would not be sufficient, for, while it relieved distention and some of the acute symptoms, it certainly in many instances would not admit of treatment of the inflamed and probably gangrenous gut. He had met with three cases of complete obstruction from bands, all of which had been relieved by operation. In patients in whom an ordinary laparotomy would probably prove speedily fatal by reason of the bad condition of the patient, Nélaton's operation would be perfectly proper as a palliative measure. The success obtained in the treatment of cases of intestinal obstruction depended, in a very large measure, upon the general practitioner, as he

was the one who usually saw these cases at the beginning.

A Story with a Moral.—Dr. Frederick Holme Wiggin said that the great mortality following operations for intestinal obstruction was due, in his opinion, to the delay in operating. The usual history was that the attending physician had purged the patient freely with salines, and had lost very valuable time before calling in a surgeon. He referred to a case in which the patient had refused operation and the friends had besought him to give morphine. He had given one dose, but, finding no amelioration of the symptoms, he had positively refused to continue its administration. Finally consent was obtained to an operation, and when it was performed it was evident, from the beginning gangrene of the parts, that had he yielded to their entreaties and continued the morphine, death would have been the result. It should be remembered that occlusion of the large intestine might exist for ten days or two weeks without any marked symptoms except vomiting. In chronic cases there was often a history of a blow or some injury which would aid one in locating the seat of the trouble. If there was a history of obstipation, and rectal examination and rectal enemata gave a negative result, there was reason for believing that the case was one of intestinal obstruction. The general practitioner often made the diagnosis of intestinal obstruction, but delayed sending for a surgeon until he had determined the particular cause of the obstruction.

Guided by the Pulse Rate to the Diagnosis.—Dr. A. Palmer Dudley said he did not believe that rectal enemata were of any value in making the diagnosis, and, more than that, he was of the opinion that they were very misleading. He was guided almost entirely by the pulse. In intestinal obstruction the pulse rate could not be brought down and kept down to a moderate figure, no matter what the form of the obstruction. A rapid pulse, with considerable thirst and vomiting and localized tenderness, were the main points on which he relied for establishing the diagnosis. He was not afraid of cases of intestinal obstruction, provided he saw them at an early stage and the patient had not previously been subjected to surgical operation. In three cases in which there had been operation previously, death occurred, not from obstruction, but from shock.

Dr. Kammerer, in closing, said that it had been his lot to see a number of cases of cancer of the bowel, occurring in young subjects. Vomiting and collapse did not come on early in cases of simple obstruction of the bowel, but they did appear later on, as a result of the constriction of the peritoneal surfaces. He could not agree with Dr. Dudley regarding the bad prognosis in post-surgical obstruction; on the contrary, his experience had been that the prognosis was better than in other cases.

Does the Theory that Typhoid Fever Can be Aborted Conflict with any Established Law of Pathology or with Any Known Scientific Fact?—Dr. John E. Woodbridge, of Cleveland, Ohio, read a paper with this title. He first quoted freely from medical literature, to show that many authorities were utterly sceptical as to the ability of the physician to cure typhoid fever or to abridge its duration. Thus, Osler says: "No known drug shortens by a day the course of the fever. We are still without an agent which can counteract the agents developing in the course of acute febrile diseases." Yet it seemed to him absurd to claim that, because no one had ever cured typhoid fever, it could never be cured. The abortive treatment, he claimed, was both rational and scientific. Ague was a specific disease, yet it could be aborted by quinine. He had been much gratified at the number of physicians who had reported favorably on his method. So far as he knew, there had been only fourteen dissenting opinions among those who had spoken from experience. He challenged the naming of one law of science which was violated in this treatment.

The Toxæmia and Not the Typhoid Ulcer Constitutes the Essence of the Disease.—One prominent argument against the possibility of aborting typhoid fever was that the characteristic feature of this disease was an ulceration of certain intestinal glands, and that, as these ulcerations took four weeks to heal, it was impossible to terminate the disease process in a shorter period. There was a fallacy, however, in this reasoning, for such an ulcer on the surface of the body, if kept aseptic, would heal in three or four days instead of weeks, and would not cause a perceptible acceleration of the pulse or respiration, or cause headache or delirium, or elevate the body temperature more than one-fifth of a degree. These other symptoms were due to the toxæmia, and it had been repeatedly demonstrated that these symptoms could be aborted while the ulcerations of Peyer's patches were far from having healed; their improvement or disappearance simply meant that the toxæmia, which was the disease, had been successfully controlled. Dr. Woodbridge said that, while he availed himself whenever possible of the aid furnished by the laboratory, those engaged solely in laboratory research were apt to be unsafe guides, intolerable masters, and dangerous leaders.

Sceptical about Aborting Disease.—Dr. William Henry Porter said that primarily the term "abortion" seemed to him a bad one, and applicable chiefly to the abrupt cutting off of intra-uterine life. The application of the term to the modification of disease seemed to him unfortunate and confusing; it would be better to speak of the prevention of disease and the shortening of its duration. Although a firm believer in the action of drugs, he was equally positive that we did not cure any disease, though we might assist nature in curing a condition which we termed "disease." He could not conceive of the possibility of the "abortion" or instantaneous arrest of such a complex condition as was found in typhoid fever. In the first place, the individual was rendered susceptible to the introduction of the germ and the toxin, and after a period of incubation the system became filled with the germs and their toxins, and, in time, the whole system assumed a pathological state. He could not conceive of a physician being able to "abort" such a condition. No doubt we could help nature in eliminating these toxins, and in this way do much to shorten the disease and diminish its intensity.

Does Typhoid Abort Itself?—Dr. M. Manges said that the reader of the paper, by his many quotations, had left some doubt as to his exact position regarding certain important points—such, for example, as the specific nature of Eberth's bacillus. If the Widal reaction was reliable, we must accept the specificity of Eberth's bacillus. He could quote more than five thousand cases, in which ninety-eight per cent. of the cases of typhoid fever had been diagnosticated by the Widal reaction. It was entirely misleading to go back to the early part of the century, or earlier, for justification of arguments, because typhus fever and typhoid fever were not properly distinguished at that time. The mere shortening of the duration of the disease was not what he understood by the term "abortion." To his mind, the real question for discussion was: "Can typhoid fever be aborted, or does it, at times, abort itself?" Every one who had seen much of typhoid fever knew that it aborted itself frequently. If we only knew the *modus operandi* of this process we could then speak intelligently of the "abortion" of typhoid fever.

Many Opportunities for Erroneous Diagnosis.—Experienced physicians were often in grave doubt

about the diagnosis of typhoid fever, even with all the advantages offered by the laboratories of the present day; yet Dr. Woodbridge insisted that we should not wait to make the diagnosis, but should proceed at once to the treatment. In the Mount Sinai Hospital, of the cases presenting the usual clinical features of typhoid fever, eighteen per cent. did not respond to the recognized reactions of this disease. It was easy to see, therefore, that there were many chances for error in collecting statistics.

Intestinal Antisepsis a Myth.—The Eberth bacillus might be in the blood, in all the organs, and in the secretions, and, if we were to abort the disease, where could we do it? According to numerous experiments, the aborting could not take place in the blood or in the various organs. The only place in which it seemed possible for it to occur was in the intestine. From a careful study of this part of the subject, he had come to the conclusion that it was absolutely impossible, in the normal individual, to disinfect the intestine even moderately. If there was any disease in which intestinal antisepsis was notoriously uncertain it was cholera, and yet cholera was essentially a disease of the intestinal tract. He did not doubt the sincerity of the position so vigorously defended by the reader of the paper, yet he could not accept it, and time alone must prove its correctness or falsity.

Shortens but Does Not Abort Typhoid Fever.—Dr. A. R. Robinson said that the term "abortion" seemed to him sufficiently accurate, if by that was intended the cutting short of the duration of the disease. Typhoid fever belonged to a class of diseases—such as scarlet fever, measles, and syphilis—in which immunity was conferred for a certain length of time. Unfortunately, even at the present time, we did not know what was meant by "immunity." The varying duration of individual cases of these diseases was probably due to the varying rapidity with which immunity was conferred upon the individual. It was well known that a woman receiving syphilitic infection through the child *in utero* recovered very quickly from the disease—in other words, she had received but a small quantity of the toxin and had been quickly rendered immune. Hence, in a general way, any method of treatment which would inhibit the life action of organisms, or reduce the amount of toxins or ptomains, should shorten the duration of the disease. The improvement in the symptoms in the cases related by Dr. Woodbridge was no proof that the specific bacilli had been destroyed; it showed only that the toxins were removed. The same was observed in syphilis after active mercurial treatment, but it by no means meant that the disease had been aborted.

Typhoid Fever Begins as a Local Sepsis.—Dr. A. Palmer Dudley said that he believed that typhoid fever was a septic fever, with a local manifestation, just as in diphtheria and in uterine sepsis. He believed it was, in the beginning, a local sepsis, originating from some point in the gut, and that the general process was secondary, just as in diphtheria. This view, of course, compelled him to believe that the treatment was essentially local—in other words, intestinal. He had had a fairly large experience with typhoid fever, and had not yet lost a single case. In a case just now convalescent, he could positively assert that he cut short the disease fully two weeks by intestinal washing and the free internal use of antiseptics. This treatment had quickly controlled the fever and caused a prompt subsidence of the other symptoms, just as was observed when, by local means, the septic process in a uterus was controlled. In order still further to inhibit germ life, it was his custom in cases of typhoid fever to keep an ice coil constantly on the abdomen, and as cold as the patient could tolerate.

Dr. Manges remarked that typhoid fever was known to exist without any intestinal lesions whatever; hence the disease was a systemic one, with, at times, a local manifestation in the bowel.

The Treatment Stimulates the Normal Antitoxins.—Dr. John Blake White said that when he had first heard of the Woodbridge treatment he had been sceptical, but had nevertheless investigated it carefully and impartially. The result of this study was that he had become thoroughly satisfied that the antiseptic treatment of typhoid fever was the true method. He exhibited several charts of recent cases in support of his position. No method of treatment, he said, would be thoroughly satisfactory if one delayed instituting it until the diagnosis had been established beyond a shadow of a doubt. These remedies stimulate the normal secretions of the intestinal tract, and these secretions act as antitoxins; hence the treatment was thoroughly rational and scientific. It was impossible for any one to say that it was or was not necessary thoroughly to antisepticize the intestine. In many cases of worms in children he had succeeded in expelling the worms by very small doses of camphor; hence one should not speak too absolutely regarding the dosage of antiseptics intended to exert their action in the bowel.

Dr. Woodbridge, in closing, said that he had been surprised at the apparent unanimity of opinion here regarding the ability of the physician to cure typhoid fever. As to the use of the term "abortion," Dr. Frank P. Foster claimed, in his dictionary, that this use of the term, as synonymous with "abbreviation," was sanctioned by good authority and was a correct and accurate use of the word. If typhoid fever was subjected to this method of treatment as early as the sixth or seventh day, it would be found almost invariably that the disease would be so mild that the patient would be walking around the house with an excellent crop of rose spots on the body. It had frequently happened to him that he had succeeded in aborting the disease, and a few days later there had been a relapse with high temperature and perhaps severe or fatal intestinal hemorrhage. He believed that antiseptics acted not only in the intestinal canal, but also in the circulation. He believed that guaiacol, at least, was capable of doing so, and in this way counteracting the toxins of the disease. The fact that Eberth's bacillus found its way through the blood and all the tissues of the body did not prove that the disease was incurable, any more than in the case of the malarial plasmodium.

THE NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 12, 1898.

Warren Coleman, M.D., Vice-President, in the Chair.

Two Cases of Abscess of the Liver.—Dr. Harlow Brooks presented a specimen from a case of abscess of the liver. It was removed from a woman, fifty-six years of age, a cook by occupation. She was admitted to Bellevue Hospital on July 15, 1897. She was of intemperate habits, but had had good health previously. Three weeks before admission she became overheated, and then began to have nausea and vomiting and pain in the abdomen. This was followed by a series of chills, with elevation of temperature. Examination showed the patient to be poorly nourished. Over both lungs posteriorly breathing was high pitched, probably because of the thin chest wall. The liver was slightly enlarged, and its free border was firm and sharp. The spleen appeared to be normal. The temperature range was somewhat like that of typhoid fever, but the Widal reaction gave a negative

result. There was some leucocytosis present. The patient died after having been in hospital about one month. No diagnosis had been made. On autopsy the lungs were found to be emphysematous, and there were several cicatrices in the apices, evidently tuberculous. The inferior surface of the right lobe of the liver was firmly adherent to the subjacent tissues, and on separation of the adhesions a large quantity of greenish-yellow pus escaped from the lower surface of the liver. The right lobe of the liver was found to be completely riddled with large abscesses, which were limited by firm walls of dense connective tissue. The cavities were lined with granulations, apparently not tuberculous. The lower wall was formed by dense peritoneal adhesions. A pin, encased in calcareous matter, was dislodged from the wall of the main abscess cavity. It was a pin of ordinary length and appearance, except that owing to the calcareous deposit it measured three millimetres in diameter. The liver, after removal, weighed two pounds and ten ounces. The gall bladder was small and contained a small quantity of light yellow mucoid secretion. The lesser curvature of the stomach was involved in the adhesions already referred to. Ten centimetres from the œsophageal opening the mucous membrane presented an old circular cicatrix, fifteen millimetres in diameter, surrounded by a ring of indurated tissue. There was no evidence of recent inflammation. The base of the cicatrix was very thin, and it was evident that at one time there had been perforation of all the coats of the stomach. This ulceration was directly below the centre of that portion of the liver containing the abscess cavity. In other respects the autopsy was negative. This was the only case he had been able to find, in which a pin had been found in the liver of a human being. He had found three cases in which foreign substances had been known to enter the liver of lower animals through the stomach, giving rise to liver abscess.

The second case was that of an Italian mechanic, thirty-seven years of age. He had had no previous illness, and denied syphilis. Three months previously he began to cough, lose flesh, and have night sweats, and this had been followed by emaciation and rapidly failing strength. He had also had pain in the right side of the chest for some time past. The expectoration was muco-purulent, and was said to have been bloody at first. Examination showed him to be poorly nourished and slightly anæmic. Over the lower half of the left side of the chest posteriorly there were marked dulness and diminished vocal fremitus. There was also dulness over the right apex, and the breathing and voice were slightly bronchial. The apex beat of the heart was normal, and the pulse was soft and regular. There was a systolic murmur over the aortic area, transmitted down the sternum. The liver and spleen were apparently normal. On introducing a needle in the eighth intercostal space on the right side posteriorly, two drachms of thick purulent fluid were removed, and then a clinical diagnosis was made of empyema. The bacteriological examination showed this fluid to be sterile and to be free from tubercle bacilli. On December 10th an incision was made in the eighth intercostal space, under cocaine anæsthesia, but on introduction of a trocar into the pleural cavity no fluid was withdrawn. The lung retracted immediately when the chest was opened. On December 13th pus was drawn from the chest, but was found to be sterile. The man was then etherized and the wound was enlarged to three or four inches in length. A portion of the eighth rib was also removed, but no pus was found. A drainage tube was inserted. On December 14th the dressings were saturated with sero-sanguineous fluid, but no pus was present. The body temperature was 103° F., and the man complained of pain. Examination of the blood showed sixty per cent. of hæmoglobin. Three days later the patient felt more comfortable and the temperature was only 100° or 101° F. A long, sterile, rubber catheter was introduced deeply into the pleural cavity, but no adhesions were found. Two drachms of slightly turbid serum followed the withdrawal of the catheter. A week later it was noted that the discharge was distinctly purulent, and on introduction of the catheter six or eight drachms of pus were evacuated. The patient died that evening. The autopsy showed an abscess cavity, six centimetres in diameter, located over the right middle lobe and surrounded by uninvolved pleura. Posterior to this was another area in which the pleural sac was covered by a purulent effusion to the depth of two or three millimetres. The cavity contained about thirty cubic centimetres of purulent fluid. The capillaries of the left pleura were injected, but there was no septic infection. The condition of the pericardial sac was negative, except that it contained fifteen cubic centimetres of clear fluid. The right ventricle contained a small quantity of ante-mortem clot. The aortic and mitral segments were slightly thickened; the valves of the right heart were normal; the coronary arteries showed a few sclerotic patches. The heart weighed nine ounces. The tissue of the right lung was collapsed, firm, and congested, and the top of the lower lobe was the seat of a broncho-pneumonia. The left lung was much congested. The branches of the pulmonary artery were distended with post-mortem clot. The surgical incision entered the right pleural cavity. The liver was large, and its capsule was smooth. The left lobe was divided so as to form a supernumerary lobe. The lower portion of the right lobe was the seat of a large abscess. This abscess cavity was lined with a thick pyogenic membrane, and contained thick odorless pus, of a light chocolate color. There was no evidence of perforation or of remaining liver tissue. The gall bladder contained fifteen cubic centimetres of dark green mucilaginous bile. There were no peritoneal adhesions. The mucous membrane of the stomach was slightly congested. There was evidence of a small ulcer, one centimetre in diameter, situated on the posterior inferior aspect, near the pylorus. It was completely healed over, and apparently had never perforated below the submucosa. No lesion of the external wall could be found, and the ulcer probably bore no relation to the liver abscess. In other respects the autopsy was practically negative. The microscopical examination of the abscess wall showed old interstitial connective tissue, covered with granulations which were not tuberculous in character. Dr. Brooks thought it probable that at the time of the former ulceration an embolus had been swept into the portal vein, and had lodged in that portion of the liver in which the abscess was found.

Dr. W. G. Le Boutillier said, regarding the second case, that he felt somewhat differently now about the diagnosis than at the time the case occurred. It would seem at first to be rather easy to differentiate suppurations of the pleura from those of the liver, especially with the aid of bacteriology; nevertheless it was impossible in certain cases. Abscesses of the liver had been known to be sterile, or to contain pyogenic germs and even the pneumococcus. If the typhoid bacillus or the colon bacillus was found in the pleural cavity, one would at once recognize that the empyema was not an ordinary one. In recent discussions regarding the treatment of empyema, a distinction had been made abroad which did not appear to have been made in this country—namely, that an empyema caused by the pneumococcus might be treated by aspiration with a good probability of recovery without further interference, while other empyemata required free incision.

Dr. George P. Biggs asked Dr. Brooks whether

lesions of the alimentary canal, particularly of the colon, had been excluded.

Dr. Brooks replied that this had been done, not only by gross but by microscopical examination. A careful search had also been made for the colon amœba, but with negative result. In the walls of the abscess there had been a few micrococci and some bacilli, apparently colon bacilli. It should be understood that the pus from the abscess cavity was itself sterile. An amœbic abscess, he thought, could be positively excluded in this case.

Cirrhosis of the Liver in a Child.—Dr. Rowland G. Freeman presented the following report: A Syrian boy, ten years old, had been admitted to St. Mary's Hospital on September 10th and had died on December 18th. There was a history of measles and whooping-cough some time before. Ten months previously there had been some illness, with fever and pain, but no further details could be obtained. One month before admission the child had developed œdema of the feet and dyspnœa, and the urine had become scanty. There had been no chills. On admission he was jaundiced; the tongue was heavily coated and moist; the urine had a specific gravity of 1.022 and was free from albumin and casts. There were marked enlargement of the abdomen, dulness on percussion, and an impulse. The liver was enlarged to three inches below the free border of the ribs. It was firm to the touch, and its upper border was at the fifth space. The spleen was markedly enlarged. The examination of the heart and lungs was negative. On September 17th he passed some tapeworm. On October 14th the urine contained a trace of albumin, and he then developed considerable ascites. Early in November a gallon of clear fluid was evacuated, and he was tapped repeatedly after that. Examination of the blood on November 19th showed sixty per cent. of hæmoglobin and slight leucocytosis. He was finally transferred to the surgical ward, and died a few days later. The autopsy was made nine hours after death. The body was greatly emaciated. The abdomen contained ten ounces of slightly turbid fluid. There was general peritonitis, with fibrinous exudate and many loose adhesions. The lungs showed chronic congestion. One bronchial lymph node, half an inch in diameter, was found to be cheesy and tuberculous. This was the only evidence of tuberculosis in the body. The anterior mediastinal lymph nodes were enlarged, but showed nothing except cellular hyperplasia. The liver was large, bound down by adhesions, and pushed upward by the distention of the intestine. It was pale and very hard, and its cut surface was of a light color. The fibrous tissue about the vessels was very distinct. There were purple areas, about the size of a pin's head, on the cut surface. The spleen showed perisplenitis. It extended to the nipple line and to the free border of the ribs. The organ was pale and rather hard. The capsules of the kidneys were adherent, and the markings were indistinct. The suprarenals were normal. The pancreas was hard. In the colon, about twelve inches above the anus, was a polypoid growth. On microscopical examination of the liver there was evidence of marked cirrhosis, with hypertrophy of the bile ducts, and very considerable increase in the interlobular connective tissue. The pancreas showed the so-called lymphoid nodules. The kidneys showed parenchymatous nephritis. The polypoid growth in the colon contained tubules lined with cylindrical epithelium.

Dr. Freeman said that cirrhosis of the liver was rare in childhood, and still rarer in infancy. It occurred mostly between the ages of nine and fifteen years. A case had been described by Oliver in an infant, three months old, and Northrup had reported in 1883 a case in a child, four and a half months old. Of one hundred and thirty cases collected by Hatfield, thirty-two were alcoholic. In the present case there was no history of alcoholism or of syphilis. In sixty-five cases collected by Howard, fifteen per cent. were alcoholic, in eleven per cent. there was a history of syphilis, and in eleven per cent. a history of tuberculosis. In some of the cases there had been preceding eruptive fevers, and in a few instances it had been thought that malaria was an etiological factor. Sections of the liver from Dr. Freeman's case were exhibited under the microscope, and also a section of the pancreas showing the lymphoid nodules.

Dr. E. Hodenpyl said that he had seen several sections from this case of cirrhosis of the liver. It seemed to him there was in the liver a very marked reproduction of the bile ducts, or rather a marked new formation of the bile ducts, and that the production of fibrous tissue was relatively enormous for the liver of such a young child. In addition to the ordinary lesions of cirrhosis there were certainly present very well-marked hyperplastic lymph nodules, not only in the liver, but also in the pancreas. In the latter they were rather numerous and quite distinct. From the history he was of the opinion that there might have been an acute infectious disease as the starting-point; probably the cirrhosis was only one of the expressions of an acute infection. These nodules had been found repeatedly in many of the acute infectious diseases, notably typhoid fever. Possibly the cirrhotic process, instead of being a chronic interstitial hepatitis, was really a replacement fibrosis, due to auto-intoxication with necrosis of the cells and their replacement by new fibrous tissue.

Dr. James Ewing said that he did not see the evidence on which was based the opinion that these small round cells were lymph nodules; they looked to him more like the ordinary mononuclear cells associated with chronic inflammation.

Dr. Hodenpyl said that the nodules to which he had special reference were sharply circumscribed, and were best seen in the pancreas. They were composed strictly of mononuclear cells, and were certainly not leucocytes. Between the cells was a fine, delicate reticulum. This was an organized tissue, in that it contained blood-vessels which traversed these small nodules.

Dr. Freeman thought the nodules in the pancreas answered fairly well to the ordinary description of the muco-lymphoid nodules occurring in typhoid fever, and sometimes in the liver.

Dr. Ewing believed that these lymph nodules were found most abundantly in the capsule of the liver, and that they were also sometimes seen in abundance throughout the section of the lobe in the livers of infants. He did not know that they were recognized as accompanying the lesions of such a cirrhosis as was present in this case.

Dr. George Biggs asked if there was any evidence to show that these lymph nodules, occurring in infectious diseases, and particularly in typhoid fever, persisted for a long time, and if they had anything to do with the development of cirrhosis.

Dr. Hodenpyl said he did not think any one knew how long they persisted. As a matter of fact, these nodules were in the capsule of Glisson.

A Case Showing the Bothriocephalus Latus.—Dr. James Ewing reported a case of bothriocephalus latus, and exhibited the worm. The specimen had been taken from a Finlander, who had been in this country for eighteen years continuously. In his childhood he had been accustomed, with the rest of his people to eat freely of raw fish. The man had evidently harbored the parasites for at least eighteen years. About the time of leaving Finland he had passed certain worms, said to be the ordinary tapeworms. There had

been no further symptoms until a month or two ago, when he had passed a considerable mass of these worms. Another interesting feature was that he had harbored four of the worms, for, although no heads had been found, there must have been four worms present, as there were four portions—two to three feet long—in which a neck of very small dimensions was discovered. A third point of interest was the fact that in spite of these four worms he had enjoyed good health, with the exception of occasional abdominal pain. He was entirely without anæmia or any other constitutional disturbance. The worms themselves were of interest in that it was believed that this worm was rare in this country. Very few such cases had been reported. Dr. Ewing said that about one month ago he had examined a collection of three hundred specimens of so-called tapeworm, used by a quack for advertising purposes. Out of this large number, all but three were the ordinary tænia; two seemed to show the broad, thick segments of tænia solium, and one was unquestionably the bothriocephalus latus. The speaker said that each segment of the tænia, or ordinary tapeworm, was two centimetres long and from one to one and one-half centimetres broad—very much longer than that of the tænia solium. The latter measured one to two centimetres in breadth, and not much more than one centimetre in length. The segment of the bothriocephalus was about four or five times as broad as it was long. Another point of distinction was the presence of the pigmented uterus. The eggs of this specimen were very abundant, and had a characteristic form. They showed a rather delicate, deeply outlined membrane, and large globules of protoplasm of immature embryo, thus differing entirely from the eggs of the tænia solium and of the ordinary tapeworm.

Oxyuris Vermicularis.—Dr. H. Heiman said that in order to bring out the points of difference between these various parasites he would place under the microscope a specimen very frequently found in children—the oxyuris vermicularis. The specimen was interesting because the entire worm was present. Eggs, almost by the thousands, were to be seen in the interior of the worm and outside of it. It was differentiated readily by the small size of the eggs and their peculiar capsule.

Dr. Le Boutillier asked if the diagnosis of oxyuris vermicularis could be made constantly by microscopical examination of the fæces—in other words, were the eggs constantly present in the fæces, or must one look for the worm itself?

Dr. Heiman replied that the diagnosis could be made by simply finding the eggs in the fæces. It was known that the worm could be recognized easily by the presence of the ova in the fæces, as they were entirely different from the eggs of the other common parasites inhabiting the alimentary canal.

Heart Muscle of Horse and Diphtheria Antitoxin; Method of Staining.—Dr. George P. Biggs presented a microscopical preparation of heart muscle, removed from a horse that had been used for the production of diphtheria antitoxin. The specimen had been hardened and stained by Markey's method, and showed the extreme fatty degeneration in a remarkably clear way. The method consisted in hardening in Müller's fluid for about one week; then in two parts of Müller's fluid and one part of osmic acid for another week. The specimen was then gradually dehydrated with increasing strengths of alcohol, embedded, and cut into sections. No further staining was needed, although a carmine stain might be employed. The osmic-acid staining of the fat globules was very well shown in the specimen presented, and it made a permanent one for purposes of demonstration. The specimen was mounted in balsam. In the specimen exhibited the degree of fatty degeneration was extreme. In the case of this horse the injections of diphtheria toxin had been pushed rather rapidly, and death had resulted in ten days from sudden heart failure.

Dr. George C. Freeborn said that, according to his experience, all osmic-acid preparations mounted in balsam faded after a time. Glycerin was the best permanent mounting for all osmic-acid preparations.

Dr. Biggs said that the specimen had been mounted only about six weeks, but had apparently not yet undergone any change.

Dr. Ira Van Gieson said that the application of this method of staining seemed to him of great importance. The ordinary method of immersing in fresh osmic acid prevented any great penetration. Moreover, the whole procedure of Markey was very convenient. Hamilton, in a recent number of *Brain*, had reported that this reaction could be obtained by taking specimens of the nervous system, carrying them through alcohol, and soaking them in Müller's fluid in which a brain had been immersed for some time. The fluid evidently extracted something from the brain necessary to produce this reaction. This modification of the process was very convenient, as by the other process the specimens were apt to become brittle. The whole reaction was very complicated. It did not seem to be the same sort of reaction that was observed with fresh fat when put in osmic-acid solution alone.

Dr. H. Brooks remarked that he had some specimens of fatty kidney, stained eight years ago with osmic acid and mounted in balsam, which were apparently as clear and bright now as when originally made.

Sarcoma of the Eye in a Child.—Dr. W. B. Noyes presented a microscopical specimen of a small round-cell sarcoma growing from the hyaline membrane lining the posterior surface of the crystalline lens. It had been taken from the eye of a child. There was also a secondary deposit around the margin of the choroid coat of the eye.

The society then went into executive session.

Clinical Department.

A CASE OF HÆMATOMA.

By J. H. McCutchan, M.D.,

Evansville, Ind.

E. C——, aged twenty-five, good physical condition, no syphilitic history, family history good, complained of bleeding at the mouth, loss of appetite, headache, and constipation. On examination of the mouth the gums were found to be covered by numerous, well-defined hemorrhagic tumors, varying in size from a pinhead to one-eighth of an inch in diameter; on further examination these hemorrhagic tumors were found to extend back over the palate and pharynx. The rest of the body was well nourished and normal in appearance; no other abnormality could be discovered at that time. The tumors were cauterized and the patient was put upon tonics, astringent preparations, and iodides. Under this treatment he seemed to recover—the bleeding stopped, the tumors disappeared, and the headache ceased. After a week's respite, however, these abnormal conditions returned in intensified form, the tumors appearing not only on the gums, palate, and pharynx, but also on the trunk, arms, and hands. Treatment availed nothing. At the end of two weeks the patient had an attack of hemiplegia involving the entire left half of the body. Speech was unimpaired and the mental faculties were retained, but there was entire loss of motion, together with partial loss of sensibility. The patient was placed upon large doses of the iodides, which seemed to have a very happy effect, but only

temporarily, as he lapsed into a comatose condition, and died two weeks after the paralytic attack.

The post-mortem examination revealed an extensive hæmatoma involving the whole motor area of the right cerebral hemisphere, the brain substance in close proximity being broken down and degenerated, while over the entire brain surface were scattered small hemorrhagic tumors corresponding in size to those found on the gums, palate, and pharynx.

A LEMON GROVE IN THE INTESTINE.

By RUFUS D. MASON, M.D.,

MISSOURI VALLEY, IOWA.

I WISH to report briefly the following case, which it seems is unique and worthy of record, as I can find nothing of the kind reported in the medical literature at my command.

I was called to see a boy, aged six years, who presented all the symptoms of appendicitis. The abdomen was tympanitic and there was very great tenderness in the region of the ileo-cæcal valve: temperature, 102° F.; bowels constipated. I gave him one grain of calomel every hour for six hours, followed by a small dose of Epsom salts. This operated freely, and, as I had instructed the parents to watch the movements to see if we could get any idea of what had brought on the attack, they found several lemon seeds. The child now fell into a low typhoid condition. The pain in the side still continued, but it was not so severe: there was only moderate tympanites: the temperature varied from 99° to 101° F., the tongue was coated, and the teeth were covered with sordes. The bowels were still constipated, so in about three days I again gave calomel, with the result of bringing away several more lemon seeds that had sprouted. Some of them had sprouts fully one-eighth of an inch long. I now kept the bowels loose, and he passed several more seeds in the same condition. His typhoid symptoms now slowly left him, and in about ten days from the beginning of the attack he was out of bed, but for some time complained of soreness in his side.

These seeds had been somewhere in the alimentary tract for at least two weeks, as he had drank no lemonade or had any means of getting the seeds later than two weeks prior to taking to his bed. I have taken out of the nose and ears of children beans and corn that had sprouted, but never before knew of anything passing through the entire intestinal tract and making an effort to grow during the journey.

CONGENITAL AMAZIA.

By ERWIN W. SCHNELLER, M.D.,

COLUMBUS, OHIO.

IN a recent issue of the MEDICAL RECORD appeared an article on "Bilateral Congenital Amazia," truly a *rara avis*, more so than the unilateral abnormality, which is of extreme rarity. However, the fact that the subject had two large normal mammillæ, with the surrounding pigmented areolæ, throws a shadow of doubt upon the possibility that this was a typical case of amastia, but rather points toward the probability that it was simply one of micromazia. Why should nature construct nipples when there are no underlying mammary glands from which the lactiferous ducts should emanate? Have any attempts ever been made to nurse the infants from these normal nipples?

I desire here to report a case of unilateral congenital amastia, which came under my observation several weeks ago. The data, taken at the time of examination, are briefly as follows:

Freddie E——, born August 29, 1894, a blue-eyed blond, is the eleventh child out of an even dozen. He presents the general appearance of a rachitic—viz., prominent parietal bosses, unclosed anterior fontanelle, chicken breast with typical rachitic rosary, pot belly, puny undeveloped legs, etc. This boy, born at six and one-half months, never nursed at the breast, never walked until three months ago, and did not begin to talk until one month later. There is no trace whatever of a mammilla on the right side of his chest, nor the slightest evidence of a mammary gland, though this is well marked on the left: this naturally causes the ribs to stand out very prominently, simulating an absence of the pectoral muscles. Froriep described a case which presented an absence of the greater part of the pectoralis major and a deficiency of the third and fourth ribs at the sternal end; such is not the condition found in my case. It is claimed by Foerster, of Würzburg, that in cases of amazia there is a concomitant lack of development of the remaining sexual organs; Scanzoni reported a case presenting absence of the ovary on the corresponding side. In my case the right testicle was found high up in the canal, simulating a monorchid.

443 SOUTH HIGH STREET.

INCISED WOUND OF THE AXILLARY ARTERY.

By FREDERICK HENRY CLEAVES, M.D.,

CONCORD, MASS.

THE rarity of this accident warrants a report of the following case:

F. T——, aged twenty-six, single, farmer, while sitting was accidentally wounded with a long, narrow, carving knife, wielded by a companion. On my arrival half an hour later I found the patient faint and unable to speak. Friends averred that he had lost at least two quarts of blood. Examination showed an incised wound one inch long, about three inches below the acromion process and through the middle portion of the deltoid muscle. I washed out the wound and tested with a probe, which passed one inch. No hemorrhage occurring, I sewed the wound.

February 13th, the arm felt well, but was seen to be puffed up about the wound, from which on pressure were exuded large clots. The wound was opened, washed, and dressed loosely with gauze.

18th, A.M., arm felt well and wound seemed almost healed. P.M., arm had ached for several hours. About fifteen minutes before I saw the patient hemorrhage occurred, which was controlled by pressure. On examination the hemorrhage was renewed, blood pouring out in a large and steady stream, pressure alone controlling it. The probe passed in two inches toward the axilla. The arm and shoulder were swollen and aching badly. I washed out the wound with hot bichloride and packed with absorbent cotton, gauze having failed to check the hemorrhage.

19th, much pain all night, despite hypodermics of morphine. Temperature, 100° F.; pulse, 100. The presence of concealed pus was feared. The arm was softer, but the upper part was quite yellow. There was no pus and very little blood was present. The wound looked healthy. When it was opened the shape of the knife blade was seen parallel to and passing through the gaping fibres of the deltoid. The probe passed three and one-fourth inches toward the axilla. A second attempt to pass the probe failed, and no opening was seen in the muscle.

20th, the axilla was hard and very tender. The whole space pulsated forcibly, and there was strong pulsation behind the axilla through the latissimus dorsi. A thrill was felt in the axillary artery below the hard swelling. The arm was one and one-half

times the natural size. Temperature, 101° F.; pulse, 86.

I now had a consultation with Dr. E. R. Cutler, of Waltham, who advised removal to Waltham Hospital for operation, where the patient was operated upon by Dr. H. A. Wood. The wound was enlarged for examination; arterial blood welled up very freely. The wound was plugged with gauze and the axillary artery was cut down upon. Hemorrhage, which was very profuse, was controlled by pressure and later by a temporary ligature. On isolating the axillary artery it was found that the knife had passed between it and a small branch—probably the posterior circumflex—very near its origin, cutting through about one-third the circumference of each vessel. Ligatures were applied to the axillary above and below the wound, including the injured branch between them, and the incisions were closed, except the opening for drainage in the original wound. The arm was, of course, cold, pulseless, and purple. It was thought improbable that a sufficient blood supply could reach it through the few small vessels above the point of ligature. The arm was then enveloped in cotton and constant heat was applied.

Next day the color was somewhat improved. Tactile sense was present, except at the back of the hand. The circulation slowly improved and motion gradually returned. Temperature, 100–103° F. during the week following the operation.

After about five weeks of very slow gain an abscess developed on the outer side of the forearm near the elbow, while the whole arm became œdematous and helpless. Pus was evacuated and a probe was passed directly down upon the ulna. The abscess healed, however, in a few days, and under constant use of passive motion and massage the œdema and disability gradually disappeared, so that on November 1st the patient was using the arm and hand without difficulty, except that he could not oppose the thumb and forefinger strongly. The color is rather leaden, and it is with some difficulty that the hand is kept warm.

A STRANGE MENTAL PHENOMENON.

By JACOB F. BUCHER, M.D.,
New Lyme Institute.

That part of the nervous system which lies within the cranium is called the brain. So important does nature consider this organ that she places it within a strong osseous box and carefully wraps it in three membranes, and to complete the protection covers that portion of the skull directly over it with an abundant growth of hair. Observing the brain closely, we see that it consists of four parts—the cerebrum, the cerebellum, the pons Varolii, and the medulla oblongata. Space will allow us to give only a suggestive description of their functions.

The cerebrum has a variety of areas, each designed to control some part of the body or to be the seat of some particular faculty. For instance, we locate the mind in the front part, and believe that all such mental phenomena as memory, will, hope, and fear originate here, while the central portion controls muscular action and governs the various muscles of the body. We are even able to locate definitely areas that control the leg, arm, and other parts. The back part of the cerebrum has to do with vision, and the parts below this preside over smell, taste, and hearing.

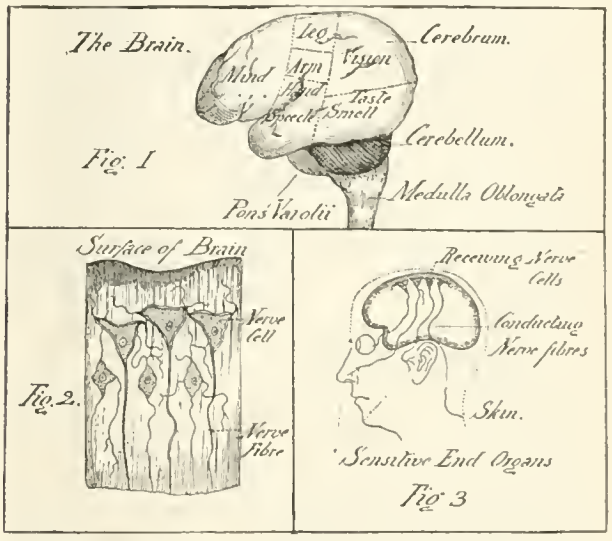
The cerebellum is largely concerned in co-ordination. By this we mean the process through which a number of muscles act in concert so as to bring about a desired movement. This portion of the brain enables us to preserve our equilibrium when walking or standing. When the cerebellum is removed from an animal, its movements become irregular and jerky and are not under control.

The pons Varolii probably has no special function. It serves to connect the other portions of the brain with each other, and is largely made up of nerve fibres. It is a large nerve cable, and is found at the base of the brain.

The medulla oblongata is frequently spoken of as the vital knot, because it contains the centres which control the heart and the organs of respiration. Besides these, it also contains many others, such as the vomiting, swallowing, and heat centres.

If a section of the brain from the front part of the cerebrum be studied under the microscope, there will be revealed two kinds of elements. One is of a cellular type, existing on the surface of the brain, and is termed the gray matter. The other is of a fibrous character radiating toward the interior, and is spoken of as the white matter. A general study of the cerebrum will reveal a similar structure throughout.

The cells making up the gray matter of the area which is the seat of the mind are large corpuscles



having distinct nuclei. They are of special interest to the physiologist, because he believes them to be the physical basis of memory. It is probable that each new impression that comes to the mind appropriates to itself a separate cell. No doubt these cells on the surface of the brain serve as pigeonholes, in which we place the records of words, faces, scenes, and all those impressions that come to us from the cradle to the grave. Perhaps some may wonder if we have enough of these little cells. We have at least a billion of them, and nature can make more if we need them. Most of us find the task sufficient completely to fill what we already have.

Not all the cells making up the mind area have to do with the memory. Many of them doubtless serve as the seat of consciousness or that peculiar mental process through which we know that we have being, or, to express it more tersely, that we are.

Memory, then, is simply a giving up of acquired impressions by certain cells to those cells in which consciousness resides. But what shall influence the memory cells to give up their impressions? This may be answered by saying that it is due to radiation. And here we must explain this term, in order that all may fully understand what we shall say farther on.

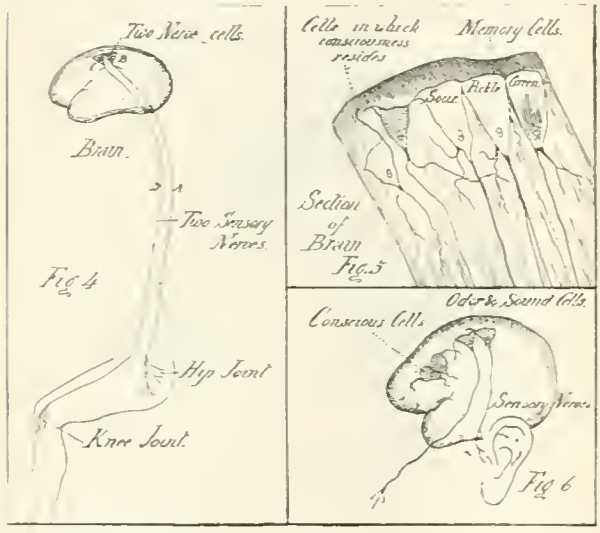
Before a mental impression can be made, there must exist a nerve cell, such as is found in the gray matter of the brain, which serves to receive the impression; a conducting nerve fibre to convey the impression received from the skin or special organ of sense to this cell; and, lastly, a sensitive surface, as the skin, and special organs, as the eye or ear, which are capa-

ble of being influenced by the forces of heat, light, and sound. In fact, every new impression that the brain receives comes through just such a channel (see Fig. 3).

As the same impression comes again and again to us, it is probable that each time it pursues the same course to reach the brain and is added to the previously acquired knowledge in some cell. And just as the impression in a certain cell is strengthened more and more by repetition, just in so great a degree is it able to give out its impression, producing exact memory.

Now it is true that oftentimes two cells which are storehouses for two unlike impressions lie side by side in the gray matter of the brain. Frequently when one of the cells receives an impression, instead of storing it without further activity, it actually agitates the adjacent cell and causes it to give up its old impression to the conscious centre, and the mind suddenly recalls something totally unexpected.

Fig. 4 is a diagram representing the sensory apparatus of the hip and knee. In certain cases of hip-



joint inflammation, the sufferer is entirely unconscious of trouble in the hip and complains altogether of pain in the knee. No amount of persuasion will convince the invalid in the beginning of his trouble that the knee is not diseased.

The explanation of the seeming transference is this. The impression which gives rise to the pain in cell *B* travels up the nerve *A* from the diseased hip-joint. The cell *B*, in storing up the impression, unduly agitates the cell *C*, which usually receives the impressions from the knee through fibre *D*, and the mind becomes conscious of the knee and its former painful impressions. We call this agitating of one cell by its neighbor radiation.

All memories are recalled by this process probably. Associated ideas recall the thing itself. To make this clearer to the reader, let me suppose that we hear the word pickle for the first time and then are led to taste a real pickle. In the gray matter of the brain (see Fig. 5) this change has occurred: A single cell has appropriated the word pickle. Clustering around this cell are other cells which have retained the impression of its form, color, odor, and taste.

If now at any time in the future after tasting of something sour you should think of the word pickle and then a vision of its form should float before your mind, you may feel sure that a process of radiation has occurred. Every one has something flash before the mind—some face, a verse, a word, not thought of for years—and has been puzzled to know how it recalled itself. In every instance careful analysis will show that it was hearing some sound, seeing some object associated originally with the recalled thing, that is the source of memory. We all know how the worn book recalls the old school faces, the smell of hay the old homestead, the little gown the baby faces. All these bring about memories through radiation. It is doubtful if we ever forget anything. The real reason why we cannot recall some things is because recollection requires radiation, and should the latter be absent the former is impossible, even if the cell were laden with memories. Radiation is the key which unlocks the mental granary, the storehouse of events.

It should be borne in mind that slight radiation stimulates memory, while if it be excessive the mind may actually experience the real impression. Recently a friend suffering from sore throat wrapped his neck in a flannel saturated with kerosene, and then went to bed. In about five minutes he seemed to hear mosquitoes humming. Thinking it a whistle of some kind, he gave it no particular attention till it persisted. Arising from bed, he found to his astonishment that the noise ceased. On going to bed the second time, the singing of the mosquitoes again became audible. A second time he arose, and as before all was quiet. This time he went to bed convinced that it was some sensory illusion. The chorus of mosquitoes started in as soon as he became quiet. For the first time he noticed the strong odor of lamp oil. Had that anything to do with these noises? That question suggested something. While he was a student at Baltimore in the fall of 1892, mosquitoes were very numerous. So annoying did they become that, no other available method being at hand, he bathed his face and hands thoroughly in kerosene. This acted like a charm, though they still persisted in buzzing around his head.

The smell of kerosene and the singing of mosquitoes consequently were strongly associated, or, to express it otherwise, two cells lying side by side must have appropriated these two impressions (see Fig. 6).

The explanation of the above circumstance is this. The smell of the oil stimulated the oil cell which had the former impression of kerosene. It being strongly stimulated, radiation occurred and the cell lying beside it gave up its old impression of mosquito voices to the conscious centre. In this instance radiation was so strong that the mind heard the real sound. This peculiar phenomenon occurred after a fatiguing day's work. Most of us experience similar things, but to a lesser degree. Usually the nervous system has been overtaxed by want of sleep, depraved nutrition, or excessive mental work. In the writer's own experience, under some conditions the eating of oyster crackers gives a strong impression of oysters—as if they were being eaten too. So oftentimes with cheese the real taste of apple pie seems to be experienced. The explanation is that they have been eaten together ever since childhood, and therefore are strongly associated.

Doubtless many delusions have their origin in excessive radiation. How often we hear it said that this or that person imagined something that no one seems to see any visible reason for. The pains and despondent spells at times experienced by all of us may be a group of mental phenomena depending largely upon radiation. We should not be too hasty in declaring imagination to be without physical cause. In our dreams we feel, see, and hear things. How do we know when awake that we are not dreaming?

Syphilis as a Cause of Abortion.—When a woman marries a syphilitic and becomes pregnant, and submits to mercurial treatment, there is more chance that gestation will terminate at term in the birth of a healthy child.—Oumet.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL REFORM—RECTAL SURGERY ILLUSTRATED BY THE LATE MR. GOWLLAND—FRESH SCANDALS—LORD WOLSELEY'S BOAST—UNIVERSITY—INFLUENZA.

LONDON, January 28, 1898.

THE Hospital Reform Association has completed its first year's work—and very hard work it has been for the honorary secretary, Mr. Garrett Horder, who has made many journeys to attend meetings and organize the profession in a number of large towns. The first annual meeting was held last week, when Mr. Horder read a paper showing the objects of the new and vigorous organization he has successfully established. As you seem to suffer from abuses of the same kind as we do, you will be interested in the work of this association. The restriction of the out-patient department is one of the first objects. On this point most reformers are agreed, but the question how to accomplish this is apt to bring out divergent views. Mr. Horder proposes *inter alia* to restrict the number of new cases admitted in the day, to bring about a more satisfactory understanding between the staff and other practitioners, and to abolish subscribers' letters. As to the last point managers of hospitals hesitate, because in many cases their rules have established a right to these letters and subscribers might resent the proposal to take it away. It is tolerably certain that some who never use the letters to which they are entitled would object, while others who have large demands upon them for this kind of assistance might go so far as to withdraw their subscriptions. I know of cases in which the subscription has been given solely with a view to obtain this *quid pro quo*. What would be the net result of abolition is therefore not easy to foresee, and most committees decline to make the experiment.

As to the limitation of the number of new cases it has been tried in several institutions with varying results. No one can doubt that there is a limit to the ability of the doctor to give his best work, and yet he ought to be at his best all through his clinic. Rejecting the twenty-sixth applicant because twenty-five have been attended to seems rather a clumsy expedient and suggestive of a lottery. The twenty-sixth might be the most important of all, so that a selection must be made by a skilled person. In large hospitals this is easy enough, but in smaller ones it might be difficult. Great importance is attached by the association to the recommendation of an outside doctor, and certainly any applicant bringing such a recommendation ought to receive attention. I believe that in practice this is done. A member of a hospital staff often receives a request from a professional man to see a case, and it may be said is always glad to do so. Such cases are usually interesting. But if patients were always required to bring such a letter, a sort of routine might become established and defeat its own purpose. Besides, general practitioners would not care to spend a considerable time in certifying the fitness of cases for charitable relief—they already sacrifice a great deal for the poor—and there is no reason why they should have this duty imposed upon them, as it would almost inevitably lead to some of their less prosperous clients asking for a "ticket" for which they could afford to pay a small fee. These questions deserve to be well threshed out and the Hospital Reform Association is doing this. I am sorry to hear that its first year's work has landed it in a debt of about £50, and hope that reformers will come forward to relieve it of this incubus.

Those who knew the late Mr. Peter Gowlland, or who saw much of his hospital work, could not fail to be impressed with his great skill as an artist. It was his custom for many years to make drawings in color of his cases, and as his specialty was rectal surgery, the great value of his accumulated illustrations will be readily appreciated. In the early part of his career he was on the surgical staff of the London Hospital and taught anatomy in the school, but these appointments he had to give up in order to meet the demands on his time made by his chosen specialty. It was not every one of his friends who had the opportunity of examining his treasures; for his modesty made much too little of them. I had that privilege, and so strongly urged him to publish his work that I was able to induce him to make a beginning by having some copies made on stone of certain drawings. But he did not complete enough and his delicate taste made it very difficult to satisfy him with lithography. Since his death I have often thought that surely some of those that were copied would yet see the light.

On Monday last Mr. Gowlland's drawings were used as illustrations to a paper which Mr. Bryant read before the Medical Society. Remarking on the too common neglect of practitioners to make a proper examination of cases which patients supposed to be piles, Mr. Bryant urged the necessity of doing so in the interest of both patients and their advisers. He said pruritus was a symptom, not a disease. As to fistula he held it necessary to trace out the indurated lines of the sinuses, all of which should be laid open in operating or failure would probably result. He had twice had to perform lumbar colotomy for recto-vesical fistula. Both operations were successful. He observed that a papilla at either the dorsal or perineal extremity of the anus usually indicated a fissure of the rectum.

Mr. Alfred Cooper strongly indorsed the practice of routine examination recommended in the paper, and mentioned the case of a patient who had been the round of eight doctors. Of these six made no examination and treated him for piles; two examined and diagnosed fissure, but the real cause of suffering was an impacted bone.

Mr. Goodsall remarked that in ninety per cent. of rectal diseases the lesion was situated within two inches of the anus.

Mr. Swinford Edwards could not accept the dictum that pruritus always indicated rectal disease, as most cases yielded to forcible dilatation of the sphincter. He objected to laying open sinuses above the internal sphincter unless they were immediately below the mucous membrane. He had had good results from injecting piles with carbolic acid diluted with four parts of glycerin.

Mr. Battle mentioned a case in which he had taken three sovereigns from a woman's rectum.

Mr. Pearce Gould remarked that on scraping a fistulous track any collateral sinuses are rendered apparent.

Hospital scandals might be thought common if the sensation-loving papers were to be trusted. Two such have been exciting attention. At the Dareuth Imbecile Hospital one of the patients became pregnant and died in childbed, having previously imputed paternity to an employee. Indignation was followed by inquiry, and the authorities blame the medical superintendent for not writing a report as soon as he discovered the patient's condition. Though he did not write a report he communicated verbally to the committee. But a scapegoat is wanted and he is to be dismissed. That is the way to whitewash managers—change the doctors.

The other case is very different—a lady met with an accident in the street and was carried into a hospital. The ankle was said to be broken, but nothing was done for some hours; then she was taken from the receiving-room, where she had been waiting, to a

ward, where the nurse washed her all over, and, though the foot was examined by two or three young gentlemen, nothing was done, and her friends who had been informed came and took her home. Inquiry was made by the managers, and the newspapers were informed that the surgeon did not intend to set the limb until the next day, as it was not in a fit state. Some further information is expected by the public, for the private doctor of the lady has written to the papers to blame the hospital.

Maidstone is not even yet quite quit of typhoid. Since I last reported there have been about a dozen new cases, raising the total of the epidemic to nineteen hundred and ten. The Town Council has taken opinions as to the responsibility of the water company and is advised that the corporation has no ground of action, as the contract (watering streets, etc.) has been fulfilled; but that individuals who have suffered loss may sue. It is probable that a test action will be brought. Other corporations and the country generally will watch the result with as much interest as the water companies.

Lord Wolseley has been boasting that we have two army corps ready to embark in an emergency and take the field. But it is calculated that only half the number of surgeons required could accompany the troops. It is time the war minister sat on the commander-in-chief.

The Duke of Devonshire gave a deputation some encouragement as to the intention of the government with regard to a London university bill.

Influenza is increasing both in London and in the provinces. Seventy-three deaths from it were registered in the week ending the 22d inst.—a higher number than any since March, 1895.

THE MEDICAL-PRACTICE LAW.

To the Editor of the Medical Record.

Sir: Under the present State law, as is very well known, every graduate of a medical college whose diploma has been granted during the last four or five years, before he can enter upon the practice of his profession must appear before a State examining-board and pass another examination for a license. For the privilege of taking this examination he must pay the sum of $25, and if he fails in more than one of the seven subjects he must wait six months before he can try again, when he must pay another $25 fee.

Now, while I am in favor of the establishment and maintenance of a high standard of proficiency on the part of those who would enter upon the practice of medicine, it seems to me that the desired end might as effectually be attained in a way that would be less expensive to the student, and, furthermore, would not subject him to the humiliation of not being allowed to practise after having received his degree from a recognized medical school.

I can see no reason why, if the State desires to establish and maintain a uniform standard, the regents should not furnish the questions which are to be the test for fitness for graduation instead of the student being compelled to submit to an examination by the faculty of his college, for which he must pay a good fee, and, having passed satisfactorily and been graduated, then to be obliged to pay another fee and pass another examination in order that he may get a license to practise.

I know from experience, and from the experience of some of my classmates, that this is a great hardship. Many are barely able financially, by practising the closest economy, to get through the required college course, and I can see no reason why this additional burden should be imposed upon them.

I am not pleading for the requirements as to scholarship, etc., to be lowered, but I do believe that the State board of regents should examine candidates as to their fitness before graduation, so that when the diploma is once granted by a New York State institution, it shall be received in this State as full evidence of its possessor's fitness to enter upon the practice of medicine.

Myron E. Fisher, M.D.

Delevan, N. Y.

THE MIDWIFERY QUESTION.

To the Editor of the Medical Record.

Sir: A paper discussing the evils of unlicensed midwifery, read by Dr. Von Ramdohr at the November meeting of the Society of Medical Jurisprudence, resulted in the appointment by that body of a committee of three physicians and two lawyers to examine the matter and report whether legislation in the premises was desirable. After examination of various statutes at home and abroad, the committee reported the advisability of such legislation, drafted a tentative bill, of which a copy is inclosed, and recommended conference thereon with such bodies as the Academy of Medicine and State and county medical societies; pointing out that the subject had been frequently discussed, especially in the latter organizations, without definite results. Subsequently that committee met in conference committees of the Academy and New York County Medical Society, when it transpired that although the proposed bill seemed adequate, providing any legislation were sought for, yet strong opposition existed to any action in the premises; it was, therefore, agreed to refer the matter back to the societies for instructions to their committees. On January 10th, the Society of Medical Jurisprudence continued its committee with power to confer with those of the Academy and New York County Society, and act in accordance with the express judgment of either, provided that no bill should be indorsed except by the society itself. On January 31st, the matter came up in the County Society, and after full discussion, in which it transpired that all the provisions of the bill were not thoroughly understood by the disputants, resolutions in favor of and against any such legislation were voted down and the matter was referred back to the committee, thus leaving the question in *statu quo*.

It seems desirable, in order that no steps be taken unadvisedly in this matter, that the medical profession generally should be apprised of existing conditions and the provisions of said bill before it takes its final shape and is introduced into the legislature.

In this State no general law regulates the practice of midwifery, *eo nomine*, and physicians differ as to whether such practice is a department of medicine or not. An apparent majority contends that labor is ordinarily a normal physiological state, attendance upon which is not necessarily an act of medical practice.

This view was taken by those officers of the New York County Medical Society charged with its prosecution when the writer first became its counsel, and he was instructed that midwives were not to be prosecuted except when, transgressing their function as attendants upon normal labor, they undertook to treat, prescribe for, or diagnosticate abnormal conditions; and under these instructions a number of midwives were convicted for acts of gynæcological practice, for the purpose of whose prosecution the existing medical law proved amply sufficient.

On the other hand some maintain that all midwifery amounts to practice of medicine; and, if this be so, no legislation is needed in the premises.

Two counties of this State, however, Erie and Ni-

agara, and one city, Rochester, do regulate midwifery under special laws and have examining-boards with power to license. In the old City of New York the health board customarily registered midwives and accepted their certificates for the purposes of vital statistics, and section 1,237 of Greater New York's charter requires "professional midwives to keep a registry of births." As a result of this custom, some physicians, many of them persons of little or no standing, undertook, and probably still undertake, to certify women as competent to practise midwifery; and so-called colleges came into existence which issued diplomas absolutely valueless to confer any legal status upon, but distinctly harmful to their recipients, who, imagining these bits of paper to be licenses, undertook to practise medicine specially. Nearly all the women above referred to as convicted in the County Society's prosecutions held papers of this sort, to which the courts refused to attach any value.

Those who oppose the licensing of midwives contend that it would confer upon them a legal status and make a permanent body of those who, left to themselves, would in process of time die out. Those favoring such licensing declare that, as the practice cannot be abolished, especially in great centres like New York City, its evils should be mitigated by regulation. Both factions agree that under present conditions the mortality of childbirth, both for mother and infant, is exceedingly great, and due largely to the ignorance of midwives and their inattention to proper sanitary measures. The former party desires absolutely to prohibit the practice of midwifery to any but licensed physicians; the latter, while admitting that this end might be desirable, believes that it is unattainable, especially so long as there exists in our cities a large foreign element that prefers, for reasons of pudicity but even more of economy, to have women in travail attended by their own sex. They believe, however, that existing evils can be minimized by proper education and sanitary regulations, and the death rate greatly reduced. The bill of the Society of Medical Jurisprudence is drafted upon the latter theory. In form an amendment to the general health law, the proposed bill devolves upon the regents of the university power to license two classes of midwives to be so designated: first, to embrace all those licensed after examination; the second, all those actually engaged in the practice of midwifery for a fixed period, one or two years, before the passage of the act, and registering within ninety days thereafter; midwives of the first class to be entitled to practise throughout the State, but those of the second only within the county where they have resided for said fixed period. This provision, while recognizing the right to continue an existing business in which a *clientèle* has been built up, would put an end to the further admission of persons not approved by the board of medical examiners. The bill aims to provide an elastic system of examination and sanitary control by lodging a large discretion in the State examining-boards and board of health respectively.

There is prevalent an erroneous idea among physicians that legislators and law officers are responsible for lack of proper regulations and enforcement of medical and health laws. As matter of fact it is safe to say, in the light of experience, that the legislature will enact almost any measure in favor of which physicians agree. The fault of our legislature from a lawyer's standpoint is not its reluctance but its overwillingness to regulate everything, even down to the feeding of sparrows and shaving of men. At the same time any project of medical legislation is apt to provoke such a multitude of objections and criticisms as to make legislators doubt what the consensus of medical opinion really is.

Before this bill or any one to the same purpose is introduced at Albany, it should be, therefore, most carefully considered and supported by such a careful and dispassionate compilation of full and accurate statistics as would carry conviction with it, and not merely by uncollated special instances which afford premises to sustain any contention. And it would be fortunate if a copy of the bill were placed in the hands of physicians generally.

As to the enforcement of law another error prevails, viz., that it is a function of district attorneys or police authorities to ferret out all breaches of statute regulative of morals or employment. Fortunately that function is beyond their physical power and they refrain from any attempt to exercise it, in most cases. The excise law is the chief exception. As to what extent its enforcement has been misused at times, we all have our opinions. It would be most deplorable if those authorities should attempt to enforce of their own initiative the medical, dental, pharmaceutical, veterinary, plumbing, pedicuring, barbering, and other laws too numerous to mention, by which various callings are regulated. Many of these statutes are administered by societies employing agents, pecuniarily responsible for malicious prosecutions, and enabled by judicious supervision to obviate or minimize the possibilities of blackmail. Except for these societies such laws would be rarely enforced. In fact, as it is they are scarcely ever enforced in this State outside of the County of New York, the prosecutions even in Brooklyn being few in comparison, and in rural districts grand juries have been known to indict the informants while letting the offenders informed against go free. Unless the medical societies should supervise the administration of a midwifery law, it is safe to presume that it would rarely be enforced.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending February 12, 1898:

	Cases.	Deaths.
Tuberculosis	173	123
Typhoid fever	12	4
Scarlet fever	172	17
Measles	305	11
Diphtheria	140	9
Laryngeal diphtheria (croup)	14	6
Chicken-pox	32	0
Cerebro-spinal meningitis	0	1
Pertussis	1	2
Erysipelas	1	0
Parotiditis	2	0

Test for Hæmatoporphyrin in Urine.—To one hundred cubic centimetres of urine add twenty cubic centimetres of a ten-per-cent. sodium-hydrate solution, and water. Wash the filtrate thoroughly with water, add absolute alcohol, then enough hydrochloric acid completely to dissolve the precipitate. Examine the solution with the spectroscope for the (two) characteristic hæmatoporphyrin absorption bands.—A. GARROD, *Centralblatt für innere Medicin*, 1897.

Physicians in Germany.—According to the latest "German Medical Calendar," there are in that country 24,393 physicians, 14,582 of whom are in Prussia, 2,612 in Bavaria, 1,785 in Saxony, 977 in Baden, 826

in Würtemberg, 588 in Hamburg, and the remainder in the smaller provinces. In Berlin there are 2,148; in Munich, 510; in Hamburg (city), 496; in Breslau, 432; in Leipzig, 379; in Dresden, 360; in Köln, 284. Berlin has 12.81 physicians for every 10,000 inhabitants. Germany boasts of 1,238 dentists and 5,254 pharmacists.

"Don't Worry" clubs are springing up all over the land. In opposition to them, the *Atchison Globe* has the following sensible remarks to make: "Don't join a Don't Worry club. Don't try not to worry. While contentment is a pleasing virtue, the people you know who are contented would be better off if they worried more. Absolute contentment and indifference to the possible troubles of to-morrow will land any one in the poorhouse. The cow doesn't worry, neither does the clam; but people are built to worry, and it was intended that they should. On the other hand, if you worry much it will land you in the insane asylum. It is the insane asylum on the one hand and the poor-farm on the other; the point is to worry just enough to keep out of both of them."

"The Ups and Downs" of Ambulance Service in this city, to judge from the almost daily newspaper accounts, almost equal those of the elevator man. One week it is a young surgeon who, on his first attempt to alight gracefully from the hind step, falls and breaks his leg and has to use the vehicle for his own transportation to the hospital. Next one reads of several wrecks in quick succession, due to an attempt to occupy car tracks at the same time that the gripman thinks he requires their services. The car's passengers are never so much agitated as is the man on the stretcher. The doctor, though sometimes hurt, usually continues on duty. The next time, however, in obedience to hospital rules, he refuses a "drunk" or "unsuitable" case, the daily papers pitch into him quite as persistently as they did before his display of heroism. One of the latest experiences recorded is that of the Roosevelt Hospital surgeon, who was driven up and down from street to sidewalk, until forced to assume control of horse as well as patient, and the driver, who has been rendered rather unmanageable by strong drink.

A "Magnetic Healer" begins the announcement of her acquirements and capabilities in the following terms: "In order to prove, and bring the success of the efforts of so many capacities in the new scientific explorerations and medical science the vital and heat magnetism as a remedy to a better observation and cure methode, and to assist, that this should by realized to the welfare of mankind." The magnetism of her words should almost effect a cure of themselves.

Elephantiasis.—In South America and the West Indies I have observed a great many instances of elephantiasis, the lymphangiomatous thickening occurring chiefly in the arms, lips, penis, scrotum, and in the labium in females.—J. M. ROHLER, *Canada Medical Record*, November, 1897.

Maidstone Typhoid Fever.—It is reported, according to a leading English journal, that steps have been taken at Maidstone to promote a combination among those of the inhabitants who have had typhoid in their houses, for the purpose of proceeding against the water company for damages. It has been decided to deliver claims upon the company, to be followed, if necessary, by a test action in the law courts. Many of the leading residents are identified with the movement.

Health Reports.—The following statistics concerning small-pox, yellow fever, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended February 12, 1898:

SMALL-POX—UNITED STATES.

TYPHOID FEVER IN THE AGED.*

BY MORRIS MANGES, A.M., M.D.,

ASSISTANT VISITING PHYSICIAN, MOUNT SINAI HOSPITAL, NEW YORK.

THE current belief in the profession would lead one to assume that typhoid fever is a very rare occurrence in the aged. This opinion is certainly warranted by the statements to be found in the text-books, even those of the most recent date. Thus J. C. Wilson, in his article on "Typhoid Fever" in the recently issued Loomis and Thompson "System of Medicine" (vol. i., page 203), refers to the rarity of the disease after the fortieth year, and says that "he once saw it in the body of a man of fifty-three." Wood and Fitz[1] assert that in the very old the disease is rare; similar statements are made by Pepper,[2] Tyson,[3] Anders,[4] Brouardel,[5] and others. These writers emphasize their statements by citing isolated cases of its occurrence at an advanced age. Thus Brouardel says the disease is rare after forty, but a number of instances may be cited. Trousseau had a case at sixty-one, Wilks at seventy, Lombard at seventy-two, Heulard d'Arcy at eighty-six, Hamernyck at ninety-two, and De Mussey one at one hundred and eight years of age. The impression given by all these writers is that these cases are, after all, very exceptional.

Other writers, however, claim that they are not so rare. Chantemesse[6] maintains this, and refers to a thesis on these cases by Josias.[7] According to Flint,[8] "the susceptibility is small after fifty, and still smaller after sixty. I have, however, met with a considerable number of cases in persons over fifty, and several in persons over sixty." Hutchinson[9] also shows that aged cases are not infrequently seen. Thus, at the London Fever Hospital, eighty-three cases out of fifty-nine hundred and eleven were in persons over fifty, twenty-seven patients were over sixty, and in two the age was seventy-five. "Bartlett long ago contended that the disease was not so rare among persons over forty years of age as was commonly supposed; and that there is really no reason to believe that the susceptibility to the causes of the disease in an unprotected person diminishes with advancing years, the immunity which elderly persons appear to enjoy being probably due to the fact that, as the disease is not uncommon in early life, they are in many instances protected by having passed through an attack." Osler, both in his text-book[10] and in the Johns Hopkins Hospital Reports,[11] gives statistics which show the frequency of these cases. Of the three hundred and eighty-nine cases treated up to May 15, 1895, five were in persons between sixty and seventy (1.3 per cent.).* Dreschfeld[12] had two cases, one in a man of seventy-five, the other in a man eighty-two years old. He states that in epidemics old people are not infrequently affected. Boy-Tessier, of Marseilles, in his recently published monograph on the "Diseases of Old Age,"[13] asserts that enteric fever is frequent in the aged.

The fact that during the present year five cases, all in persons over sixty years of age, have come under my observation, leads me to believe not only that typhoid fever is not an infrequent event among the aged, but that its presence often is overlooked. Two of these cases occurred on my service at the Mount Sinai Hospital, one being in a woman of seventy-two, the other in a man of sixty-three. The third case was in a man of sixty-two years, a patient of Dr. Albert Kohn, of this city. The other two were patients of Dr. J. Rudisch—one, a man of sixty-five, being a private patient; the other, a man sixty-five years old, is at present on his service at the Mount Sinai Hospital. The details of these cases will be considered later; suffice it to say at present that three of them were typical in their course; the other two, however, presented the clinical picture of pneu-

* Read before the section on general medicine, New York Academy of Medicine, November 13, 1897.

* Since the above was written, an additional case has been reported from Johns Hopkins Hospital by Flexner and Harris (*Johns Hopkins Hospital Bulletin*, December, 1897, p. 259). The patient was sixty-eight years old; he died two days after admission. The symptoms were atypical; his chief complaint was dyspnœa for the preceding two weeks. At the autopsy no intestinal lesions were found, but there was a thrombosis of one of the main branches of the pulmonary artery with consecutive gangrene of the lung and pyopneumothorax. Typhoid bacilli were found in cultures which were made from many of the viscera.

monia. Attention has also been called to the fact that these senile cases are often marked by an insidious onset, by vagueness of the usual symptoms, and by a marked and increasing asthenia. These features, combined with the current belief that the disease is so exceptional in the aged, render it very possible that it is occasionally mistaken for other conditions. The most striking corroboration of this contention is furnished by the statistics of the New York board of health, which have been most courteously placed at my disposal by Dr. Tracy.

When it is noted that this report includes only the fatal cases, then the actual number of cases of this disease which have occurred among the aged in this city during the past ten years is quite surprising. The percentage, as calculated from the above table of 3,644 deaths, would be 11.3 per cent. for the forty-fifth to sixty-fifth years (414 deaths), and 2.6 per cent. for sixty-five and over (96 deaths). The total percentage of deaths in persons over forty-five years is 14.

To ascertain the actual proportion of cases, I applied to Dr. W. H. Park for the ages in the cases in which the Widal reaction was obtained. Dr. Park has kindly prepared the following table of the one hundred and twenty-five cases in which the patient's age was given:

CHART II.

AGES OF PATIENTS IN WHOM THE WIDAL REACTION WAS FOUND BY THE NEW YORK BOARD OF HEALTH.

Years.	Number of Cases.	Actual Ages.
1 to 4	5	2, 3, 3, 4, 4.
5 to 9	13	
10 to 14	20	
15 to 19	6	
20 to 24	23	
25 to 29	26	
30 to 34	9	
35 to 39	9	
40 to 44	7	
45 to 49	3	45, 47, 47.
50 to 54	1	52.
55 to 59	2	57, 59.
60 to 64	0	
65 to 69	1	65.
70 to 100	0	

Total number of cases under 45, 118; 95 per cent.
Total number of cases over 45, 7; 5 per cent.

NOTE.—Only the one hundred and twenty-five cases are included in which the age could be ascertained.

Symptomatology.—In quite a large number of cases the symptoms differ in no wise from the ordinary course of this disease. In others, however, they are different, following no regular type. The onset is insidious, resembling some simple gastric or intestinal disturbance. The typical headache is often absent; epistaxis is infrequent; the fever is less marked and is very irregular in its course. Subnormal temperatures are not infrequent. The roseola is frequently absent, or, if it is present, is very scanty. The abdominal symptoms are not pronounced; the enlargement of the spleen is either slight or it may be wanting. Boy-Tessier[13] calls attention to the fact that the abdomen may become distended owing to the senile relaxation of the tissues. Severe hemorrhages from the bowels are common. Perforations of the intestines have also been reported. The pulmonary symptoms are always pronounced, the bronchitis is always marked, while congestion, hypostasis, and pneumonia are very common and often lead to faulty diagnoses, as occurred in Cases I. and II., and in a case reported by Osler,[14] as follows:

"George W. K——, aged seventy (hospital No. 1,814), admitted September 22, 1890, complaining of extreme debility. Patient states that he has been a healthy man, but cannot give a satisfactory account of himself. He states that he has not had cough, and that the bowels have been regular; no chills, no vomiting.

"On admission he was much emaciated, looking in a condition of senile debility. The temperature was 97.5 F. at 8 P.M., and did not rise above 97° F. throughout the night. Pulse, 72, regular, compressible; radials sclerotic. Tongue very heavily coated, dry, and almost black. There were numerous cutaneous hemorrhages about the wrists and legs, and large superficial ones on the skin over the manubrium and scattered over the trunk. The chest was somewhat barrel shaped and the lower part of the sternum was much depressed—a modified 'Trichterbrust.' On the first day nothing was noticed on the examination of the lungs. The heart sounds were clear; second aortic accentuated and ringing.

"Note on the abdomen reads: 'Soft, irregularly distended; the intestinal peristalsis can be seen through the thin walls. No tenderness; no growth felt. Percussion limits of the spleen and liver are normal.'

"The patient was thought to have a senile cachexia, and was ordered stimulants, with iron and nourishing food. The urine contained a moderate amount of albumin, with granular and hyaline casts. During the 23d, 24th, and 25th, there was fever, the temperature rising to 101° F. It was usually normal, sometimes subnormal in the morning. There was no diarrhœa. He had no cough, no expectoration. The physical examination was negative. On the 27th he began to have diarrhœa. He was unconscious; tongue very dry; he passed urine and fæces involuntarily. The ecchymoses on the chest were more extensive. To-day it was found that the percussion note at the left base was dull as high as the angle of the scapula. Respiration was tubular, expiration prolonged, and there were a few râles. It was then thought that it was a case of pneumonia in an old, debilitated individual. He became progressively weaker on the 28th, and died on the morning of the 29th. The diagnosis was pneumonia in an old man.

"Autopsy (Dr. Welch). Anatomical diagnosis: Typhoid fever, recent croupous pneumonia of the left lower lobe, enlarged spleen, gall stones.

"Peritoneum smooth; the peritoneal surface of the ileum near the valve was covered with streaks of dark-red hemorrhagic infiltration. The small intestine presented a number of ulcers; the largest were in the lower part of the ileum. They were irregular, nearly always as deep as the transverse muscular coat, and with little or no thickening, and without adherent sloughs. Many had dark-red hemorrhagic floors. One occupied the margin of the ileo-cæcal valve. They extended upward for a distance of fifty centimetres. There were also many small follicular ulcers. The edges of the ulcers were but little undermined. In the cæcum and beginning of the colon were several small ulcers; glands moderately swollen and soft. There was no trace of tubercles over the ulcers, which were undoubtedly typhoid in character.

"The spleen was soft, and weighed two hundred and sixty grams.

"The heart was small; valves presented calcareous plates.

"The lobe of the left lung was in a condition of recent hepatization, the remainder of the lung emphysematous. There was much œdema.

"The kidneys were anæmic and were in a state of cloudy swelling.

"This interesting case of typhoid in an aged man presented no clinical features in any way characteristic. He was admitted in a cachectic condition, with dry, furred tongue, and when the consolidation in the left lower lobe was detected Dr. Lafleur, under whose care he came, thought very naturally that it was an instance of slowly developing pneumonia in an old man—that

the 'typhoid state,' so well marked, was secondary. With this opinion, I, seeing him two days before death, concurred. Unfortunately no details could be obtained as to the length of time the patient had been ill. It is interesting to note the low temperatures. On four or five occasions within the first three days he was in the hospital the temperature was below 98° F., and once was 97.5 F. In the week he was under observation only once did the temperature rise above 102° F. The extensive cutaneous hemorrhages were such as are seen frequently in the protracted cachexia of elderly people."

Boy-Tessier believes that these pulmonary conditions are possibly dependent more upon infarction and atelectasis than upon hepatization. Nephritis is of frequent occurrence. Asthenia is always a marked feature; the patients look very ill—in fact, more so than the symptoms present would seem to warrant. The heart action is always poor, and the pulse very soon shows the struggle under which the heart is laboring. The duration is very irregular, and the convalescence is always protracted. Death often occurs from syncope. Mental symptoms, especially loss of memory, have often been observed during convalescence. Relapses may occur.

The cases which I have to report are as follows:

Case I.—Mrs. M. A. S——, seventy-two years old, was admitted to my service at the Mount Sinai Hospital on January 3, 1897. She had been an inmate of the Chapin Home, where Dr. Mandelbaum had had her under his care and had made the diagnosis of typhoid fever.

Family history negative.

Previous history: Had had some lung trouble thirty-five years ago; has had a cough ever since.

Present history: Some eight weeks previously she had visited some friends in Harlem, who had typhoid fever. She has not been well for six weeks; had a number of severe chills at the beginning of her illness, and had what was called influenza. For the past week she has had severe headaches and fever, anorexia, vomiting, poor sleep; bowels constipated; she has had a number of fainting-spells, the attacks being anginoid in character; has some cough, with expectoration and dyspnœa. No urinary symptoms. She complains mostly of oppression over the thorax, some abdominal distress, and pain on swallowing.

Condition on admission: She is emaciated, anæmic, and looks sick. The tongue is dry, cracked, and heavily coated.

Lungs: Anteriorly, dull note over right side, with crepitant and subcrepitant râles; increased voice and breathing. Posteriorly the same.

Heart: Negative as to murmurs, but action feeble.

Abdomen: Slight general tenderness; a few typical roseolæ over chest and abdomen.

Liver: Negative.

Spleen: Slightly enlarged to percussion, but not palpable.

On admission, at 1 P.M., pulse, 100; respiration, 26; temperature, 102° F. Fluid diet ordered; cold applications to the chest every three hours; strychnine and whiskey.

At 6 P.M., pulse very irregular; temperature, 103° F. At midnight 102.6° F.

January 4th, urine reported acid, amber, turbid; specific gravity, 1.020; trace of albumin, no sugar, few pus cells, urates, granular casts. Pulse between 84 and 90, at times irregular and intermittent. Temperature, 8 A.M., 101.2° F.; 8 P.M., 101.8° F. Four small movements, urine scanty.

January 5th, complains especially of weakness; pulse same, ranging between 84 and 96. Temperature, 8 A.M., 100.4° F.; 8 P.M., 101.2° F. Tincture of digitalis, five minims every six hours. Two stools. Urine same.

January 6th, general condition same until 4 P.M. At 8 A.M., temperature, 102.2° F.; pulse, 124; respiration, 24. At 4 P.M. had a severe chill, lasting fifteen minutes. At 5 P.M. temperature rose to 105° F.; pulse, 114; respiration, 30. Involuntary stool. At 8 P.M., temperature, 103.8° F.; respiration, 24; pulse, 100. Three stools during the night.

January 7th, temperature gradually came down, being 100° F. at 8 A.M.; respiration, 24; pulse, 78. At 8 P.M., temperature, 99° F.; respiration, 24; pulse, 80. One stool.

January 8th, comfortable all day. At 8 A.M., temperature, 97° F.; respiration, 24; pulse, 86. At 8 P.M., temperature, 98.2°; respiration, 24; pulse, 90.

January 9th, in early morning was nauseated and vomited nourishment. Digitalis changed to sparteine, one-half grain every three hours. Nausea stopped. During the day pulse bad. Bowels to-day and yesterday had to be moved by enema. Urine, forty-eight ounces. At 8 A.M., temperature, 100° F.; respiration, 22; pulse, 86. At 8 P.M., temperature, 100° F.; respiration, 24; pulse, 90.

January 10th, nausea has returned, and she still complains of pain in the throat; bowels must still be moved by enema; urine, sixty ounces. At 8 A.M., temperature, 100° F.; respiration, 24; pulse, 76. At 8 P.M., temperature, 100.6° F.; respiration, 24; pulse, 96.
